**PHARMACOLOGY**

Knowledge of drug interactions assists in the diagnosis and care of substance abuse victims. A careful medication history for all legal and illegal drugs, including ethanol, may pinpoint the source of an adverse reaction. For example, a variety of agents can increase the effects of cocaine. Some abusers ingest small amounts of organophosphates to decrease pseudocholinesterase activity and prolong the effects of cocaine. The co-ingestion of ethanol and cocaine results in an active metabolite, cocaethylene, which also enhances and magnifies cocaine’s effects. Serotonin syndrome, manifested by muscle rigidity, hyperthermia, diarrhea, and seizures, may result when sympathomimetic drugs are taken concurrently with selective serotonin reuptake inhibitors such as fluoxetine. Amphetamines elevate serotonin either directly or by reversible inhibition of monoamine oxidase (MAO). In fact, a selective serotonin reuptake inhibitor can result in flashbacks in prior amphetamine users. MAO inhibitors can provoke hypertensive crisis in patients taking sympathomimetics. Interactions between agents commonly prescribed for patients with human immunodeficiency virus (HIV) and recreational drugs may be associated with serious clinical consequences because protease inhibitors and nonnucleoside reverse transcriptase inhibitors can inhibit or induce the cytochrome P450 system.

Some common chemicals in the home and workplace have an intoxicating effect that may be unexpected. Solvents, paint, laquers, glues, aerosols, refrigerants, and other propellants are readily accessible for abuse among children and teens. Inhaled hydrocarbons, such as toluene, are rapidly absorbed and easily pass through the lipophilic blood-brain barrier to give an inexpensive high.

Illicit drug laboratories have poor quality control, and many drugs are combined or “cut” with other substances to increase profits. Up to 50% of street samples lack the alleged drug. Some additives, such as local anesthetics or sugars, may be innocuous, but others, such as strychnine, may be lethal. Other drugs, such as PCP, are misleadingly sold as a different drug, such as lysergic acid diethylamide (LSD). During the 1990s, many doses of purported Ecstasy (MDMA) actually contained amphetamine drug mixtures or even simple caffeine or ephedrine. Drug combinations and unanticipated additives or substitutions may produce a clinical picture discordant with what the patient claims to have taken.

“Look-alike” drugs may also have toxic effects. Teens in particular may take look-alike or “knock-off” drugs that look like a desired product such as Ritalin or Coricidin in the hopes of getting a desired “high,” when in reality they may suffer unanticipated effects from an unrelated medication sold by an unscrupulous dealer.

**CLINICAL FINDINGS**

**History**

A drug history should be obtained from patients reporting drug reactions, acute anxiety or other psychiatric problems, and acute cardiopulmonary or neurologic symptoms. This information should include use of legal and illegal substances, prescription and OTC medications, vitamins, herbs, tonics, and potions. When appropriate, the physician should specifically ask if the patient is suicidal. The physician who is neutral and nonjudgmental in approach is more likely to obtain accurate information.
Patients should be asked what they believe their son or daughter took and when. The “street name” may be unfamiliar to the emergency physician; for a list of more than 2300 street terms that refer to specific drugs, visit http://www.whitehousedrugpolicy.gov/pdf/street_terms.pdf.16 Regardless, this is no guarantee that the purported ingestant is pure or unadulterated; therefore, history is no substitute for careful examination, which may provide more reliable clues. Nonhospital personnel, family members, and friends may be able to offer additional information. Patients who are brought from the scene of a club, “rave,” or circuit party with altered mental status may be under the influence of a “club drug” such as MDMA (Ecstasy), GHB, flunitrazepam (Rohypnol), or ketamine. Other club drugs, such as “Verve” and “Jolt,” are sold on the Internet as precursor molecules to GHB, known as γ-butyrolactone. These dangerous drugs are especially appealing to teens.17

Intravenous drug abusers are likely to have infectious complications such as septic pulmonary emboli, skin or brain abscesses, endocarditis, or HIV-related disease.

The RAFFT score is useful in detecting substance abuse in adolescents, and a positive response to one or more of the following questions warrants further evaluation18:

**Relax:** Do you drink/use drugs to relax, feel better about yourself, or fit in?
**Alone:** Do you ever drink/use drugs while you are by yourself, alone?
**Friends:** Do any of your closest friends drink/use drugs?
**Family:** Does a close family member have a problem with alcohol or drugs?
**Trouble:** Have you ever gotten into trouble from drinking or using drugs?

**Physical Examination**

Documentation of vital signs is essential. Although fever may suggest infection or drug reaction, temperatures are frequently neglected in violent or agitated patients. Because rapid mouth breathing, dry mucous membranes, and agitation all produce unreliable oral temperatures, a rectal temperature can confirm suspected hyperthermia. Patients should be undressed and completely examined, with particular attention paid to the skin, eyes, and nervous system.

Physical examination includes evaluation for specific toxidromes. The presence of diaphoresis, mydriasis, tachycardia, hypertension, abnormal mental status, and hyperactive bowel sounds suggests sympathetic overload. In comparison, anticholinergic syndrome has these same features with the exception of dry skin and mouth and absent bowel sounds. The neurologic examination should incorporate a mental status evaluation, addressing both the level of consciousness and appropriateness of affect. Dental disease, with extensive caries, has traditionally been attributed to methamphetamine use, but it is common in other forms of chemical dependency.19

The skin provides important clues to substance abuse, such as residue of drugs on the hand or face or track marks from intravenous drug use.

**DIFFERENTIAL DIAGNOSIS**

It is dangerous to assume that abnormal behavior or altered mental status in the unkempt young patient is due to drug intoxication. Many serious illnesses can manifest as an overdose (“OD”), including sepsis, meningitis, encephalitis, head trauma, unintentional poisoning (e.g., carbon monoxide), hypothermia, heatstroke, intracranial hemorrhage, complex seizures, and drug withdrawal. Hypoglycemia and other metabolic and endocrine derangements are important considerations. Similarly, drug intoxication should be considered in the differential diagnosis of altered mental status or abnormal vital signs regardless of age.

### COMPLICATIONS

Illicit drugs produce a wide variety of complications involving all major organ systems. They are responsible for up to 5% of intensive care admissions, generating 10% of costs. Neurologic complications are especially prominent. Almost 10% of strokes occur secondary to drug abuse.21 Cerebral infarction, cerebral and cerebellar hemorrhage, and subarachnoid bleeding are often secondary to use of cocaine and amphetamines and, occasionally, PCP or heroin.22 Single generalized tonic-clonic seizures are common with substance abuse, and status epilepticus can occur. Although sympathomimetics such as cocaine and amphetamines are responsible for the majority of seizures, heroin, tricyclic antidepressants, and PCP play a significant role. Withdrawal from benzodiazepines and alcohol can also result in status seizures.

The dangers of substance abuse extend far beyond the toxic effects of a particular drug. Associated hazards include HIV infection, not only secondary to intravenous injection but also from the promiscuous lifestyle associated with the drug culture. HIV seroprevalence is 12.7% among injection drug users and 7.5% among crack smokers.23

Recent declines in HIV incidence among intravenous drug abusers are encouraging, but resurgences have been associated with needle sharing and inadequate methadone treatment.24 Accompanying this phenomenon is a decrease in hepatitis B and C among injection drug users in some U.S. cities.25 Almost 20% of cocaine abusers have a positive skin (tuberculosis) test result in some locales. Sexually transmitted disease is common, especially in the sex-for-drugs culture of crack cocaine. Syphilis in particular is endemic among crack abusers.

The lungs are target organs for impurities in intravenous drugs, and pyrogens become trapped in this massive filter. This can produce “cotton fever,” characterized by high fever, tachycardia, and tachypnea 10 to 20 minutes after injection.26 This benign self-limited illness contrasts with the long-term restrictive and obstructive lung diseases that accompany the prolonged intravenous abuse of methylenidate. Right-sided endocarditis is a frequent sequela of chronic intravenous drug abuse, and the nonspecific flulike symptoms that accompany this disease can mislead the clinician. In addition to endocarditis and acquired immunodeficiency syndrome, intravenous drug abusers develop septic pulmonary emboli, cellulitis, botulism, tetanus, and other infectious complications. They may develop unusual sites of osteomyelitis or septic arthritis involving the lumbar spine or sternoclavicular or sacroiliac joints.

Psychiatric complications of substance abuse are frequent and include anxiety, depression, suicidal ideation, mood swings, paranoia, and panic attacks. Paranoia and depression and associated suicide attempts are common among stimulant abusers, and hallucinations of parasites under the skin (formication) are frequent in those addicted to amphetamines. Sympathomimetics are strongly associated with aggressive behavior and street crime. Traumatic injuries are endemic among substance abusers and arise from both assault and motor vehicle crashes. In addition, psychedelic drugs, such as LSD and PCP, can prompt extreme behavioral change that can in turn lead to traumatic injuries. Occasionally, trauma can be occult, and the unwary physician may overlook a stab wound in a
patient whose clinical picture is predominated by drug-induced agitation.

## DIAGNOSTIC ADJUNCTS

All patients with acute alterations in mental status require either a bedside glucose test strip measurement or the empiric administration of 50% dextrose solution. Patients who are unstable hemodynamically or with altered mental status need assessment of electrolytes, blood urea nitrogen, and creatinine. The complete blood cell count is of little value, except to follow serial hemoglobins if occult trauma or hemolysis is suspected. Arterial blood gas may be useful in assessing acid-base status as well as measuring oxygenation and ventilation. Rhabdomyolysis, most likely seen with sympathomimetic abuse or prolonged periods in the same body position as may occur with abuse of downers (e.g., barbiturates), is best detected by measurement of serum creatinine kinase or myoglobin.\(^{27}\) Rhabdomyolysis is usually defined as creatinine kinase levels more than five times the upper limit of normal. Dipstick urinalysis may screen positive for hemoglobin without accompanying red blood cells but is insensitive for this condition. The electrocardiogram will occasionally diagnose a myocardial infarction in patients with drug-related chest pain.

The use of qualitative toxicology screens is controversial, but these are less important than the patient history and clinical status. Although unsuspected drugs may be detected, this knowledge rarely affects acute patient management.\(^{28,29}\) Emergency physicians are often confused about which drugs are screened for on their own hospital's toxicology panel. Quantitative levels of suspected substances, such as acetaminophen or acetylsalicylic acid, may be valuable in certain circumstances. A new generation of rapid bedside urine toxicology screens may provide timely information, but their use requires further study.\(^{30}\)

## MANAGEMENT

### Agitation

Few antidotes exist for psychoactive drug intoxication, and with a few notable exceptions, treatment is supportive. Violent or agitated patients require sedation. Benzodiazepines such as lorazepam (Ativan) can best sedate patients with sympathomimetic symptoms, whether due to drug intoxication or withdrawal. For other patients, intramuscular butyrophenones, such as haloperidol (Haldol) and droperidol (Inapsine), are rapidly effective and generally safe; however, droperidol has a black box warning from the Food and Drug Administration (FDA) for QT prolongation and potentially torsades de pointes. In September 2007, the FDA added a warning stating that "torsades de pointes and QT prolongation have been observed in patients receiving haloperidol, especially when the drug is administered intravenously or in higher doses than recommended. Haloperidol is not approved for intravenous use."\(^{31}\) Phenothiazines are not recommended in the drug-intoxicated patient because of their strong anticholinergic effects and potential to produce hypotension and lower the seizure threshold.

### Body Packers and Stuffers

The body stuffer swallows loosely packaged drugs, or the raw drug itself, in an attempt to conceal contraband on arrest. The body packer (a "mule") delivers professionally packaged drugs in his or her intestines, usually on a flight from another country. In many cases, these packets can be visualized radiographically.\(^{32}\)

There is considerable debate regarding the best approach to these patients; some recommend activated charcoal for body stuffers and whole bowel irrigation for body packers, whereas others adopt a less aggressive approach.\(^{33,34}\) In asymptomatic cases, the patient's right to refuse care usually supersedes local laws for forcible removal of such evidence. Patients who are significantly confused from drug effects (or comatose) are incapable of refusing lifesaving interventions.

### Referral

After acute medical issues have been managed, substance abusers should be asked whether they would like help in overcoming their addiction. Studies show that intervention may be most successful for abusers of heroin, nonprescribed methadone, and benzodiazepines. Users of crack cocaine appear to be more resistant to treatment.\(^{35}\)

### Drug Seeker

As the front line in medical care, EDs are confronted by patients with drug-seeking behavior, typically for pain medication or benzodiazepines. Although only 1% of ED patients have a formally recorded diagnosis of substance abuse, as many as 27% of ED patients are actually in need of substance abuse treatment.\(^{36}\) This drug-seeking behavior is described as a compulsion for seeking and taking drugs after prolonged use of a certain drug.\(^{37}\) Although physicians should not “feed the habit” of drug seekers, their quandary is that inadequate pain management is internationally considered poor medicine and unethical.\(^{38}\)

EDs need to judiciously provide pain medication to avoid long-term problems from undertreatment of real acute pain. However, an overly liberal approach can contribute to addictive behavior with repeated drug seeking. It is difficult for the individual physician to screen effectively for drug-seeking or abuse on just a single encounter. Self-admission would be the easiest screen, but 90% of patients who abuse opioids deny it.\(^{39}\) Although not sensitive, a prior history of drug or alcohol abuse may identify patients at risk for abuse of opioids, the most commonly abused agents of the prescription drug seeker.\(^{39}\) Repeated visits for the same complaint, rapid dose escalation, unusual and multiple allergies, and demands for specific agents (often in specific milligram amounts) are all warning signs of potential drug seeking.\(^{39,40}\) Unfortunately, there is no reliable finding that can consistently identify drug seeking while not penalizing legitimate medication seekers.

In response to this problem, both individual hospitals and some states are starting to track patients who habitually receive opiate prescriptions.\(^{41}\) The effectiveness of such programs is not known. Some locales have had success with pain guidelines that restrict the use of narcotics to proven conditions, with electronic flagging of habitual visitors who present for medical care.\(^{41}\) Such approaches may work if done in conjunction with referral to chronic pain clinics or detoxification centers. A multipronged approach that combined counseling, denial of narcotic prescriptions in the ED, and referral to a single pharmacy resulted in a 72% decrease in ED visits by frequent users.\(^{42}\) Restriction or removal of meperidine (which is highly intoxicating with potential for serious adverse effects) from EDs can result in decreased visits and fewer substance-abusing patients.\(^{43}\)

Beyond facility-wide policies, individual physicians can attenuate drug-seeking behaviors. Avoiding the use of meperidine, which reinforces drug-seeking behavior, is an excellent
strategy. In addition, the use of long-acting narcotics such as methadone and specialized forms of oral morphine decreases the reinforcement of drug-seeking behavior while providing compassionate pain alleviation. Finally, concerned refusal, explaining to the patient that opioids or other controlled substances are not appropriate, may be helpful but only if other physicians in the group or community agree on such a strategy for a particular patient.

**KEY CONCEPTS**

- Substance abuse can affect people from all socioeconomic groups and all ages.
- For the majority of patients with toxin-induced violent behavior, intramuscular butyrophenones such as haloperidol (Haldol) are safe and rapidly effective sedating agents. In patients with suspected sympathomimetic (e.g., cocaine and amphetamines) intoxication, benzodiazepines such as lorazepam (Ativan) should be utilized.
- Presenting to an ED with a complication of substance abuse may be a “teaching moment.” Substance abusers should be offered drug treatment services.

**CHAPTER 185**

Evaluation and Management of Children with Special Health Care Needs

*Terry Adirim*

---

**PERSPECTIVE**

Children who are developmentally or physically disabled, have chronic illnesses, or are technology dependent for mobility or survival have special health care needs. In 1998, the Federal Maternal and Child Health Bureau provided a definition of children with special health care needs (CSHCN) to assist states in their systems development activities. This definition was conceived with the input of various constituencies, including CSHCN program directors, parents, and health care professionals. The following definition has become widely accepted within the pediatric community:

“Children with special health care needs are those who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally.1

The prevalence and characteristics of the CSHCN community depend on the definition used. Using the federal definition, in 2001 it was estimated that almost 13% of children in the United States experienced a special health care need.2

There was a higher prevalence among older children, boys, and non-Hispanic white and black children, and after adjustment for demographic factors, families in poverty were more likely to have a CSHCN.

Advances in medical science and technology have been instrumental in allowing children with complex medical problems to survive beyond the neonatal period. Moreover, family-centered care has been the goal for the care of these children and, as a result, many are living at home instead of in institutions. These children are frequent users of the emergency medical system. Acutely ill children with special health care needs account for 24% of pediatric emergency department (ED) visits at tertiary care hospitals.3 Emergency medical services (EMS) are typically activated during the time of a crisis. This crisis may occur because of equipment failure or panic by the caregiver who is fatigued or new to caring for the special needs child. However, a survey of 100 families with CSHCN conducted at a tertiary care urban pediatric center demonstrated that although 97% of the families had sought emergency care in the past, only 23% of the caregivers had ever called 911 before, and 93% had driven their child to the hospital during an emergency. Families may transport their children either to the nearest community hospital or to their “home” institution, which is likely to be a tertiary care center. Most EMS jurisdictions transport to the nearest “appropriate” medical facility.

Children with special health care needs are usually cared for by adults who have been trained to manage their child’s daily care. In general, families are knowledgeable about their child’s medical conditions and technological needs. Families may have detailed medical plans that specify such things as the size of tubes, how often to change tubes, dosages of medications, and ventilator settings. One example of a program that provides information to medical caregivers is the American Academy of Pediatrics and American College of Emergency Physician’s “Emergency Preparedness for Children with Special Health Care Needs Program.”3 This is an emergency notification program whose purpose is to communicate specific information to medical caregivers about the special needs child’s conditions and medications. An emergency information form (EIF) is completed by the child’s primary care physician or family and is carried with the child. Programs have also been developed to assist EMS personnel, such as “EMS Outreach,” a tertiary care hospital–based program developed in the Washington, DC, metropolitan area. Enrollees in the EMS Outreach program complete a medical information form that caregivers carry with them. This information is disseminated to area EMS systems so that EMS providers are aware of the specific needs of the CHSCN within their jurisdictions. The information is kept in a database and is updated every 6 to 12 months. Although most caregivers are adept at handling many of their children’s emergencies, caregivers seek help for a variety of reasons, including the need for respite, equipment malfunction, an overwhelming medical problem, and help with transport to the child’s home hospital.

**PRINCIPLES OF DISEASE**

**General Issues for Children with Special Health Care Needs**

CSHCN differ from well children in a variety of ways. Some CSHCN may be neurologically impaired and therefore developmentally delayed. Their physical growth may be limited, resulting in their being smaller than other children of the same age. As a result, medical personnel cannot rely on age- and weight-based norms and should either ask caregivers for this information or use length-based tapes when estimating weight, calculating drug dosages, and determining fluid management. Developmentally delayed children may have vital signs that differ from those expected for “healthy” children of the same age. For example, baseline vital signs are altered in children...
with cardiac conditions or on mechanical ventilators, and a child with unrepaired complex congenital heart disease may have a baseline pulse oximetry reading in the low 80s. Some children with lung diseases may have respiratory rates higher than expected, yet these higher respiratory rates are considered their baseline. Also, some children may have sensorineural deficits such as blindness and deafness that may make assessment challenging. Medical care providers need to be aware of these situations.

Care must be taken when treating and moving developmentally delayed children as they tend to become frightened easily with quick motions and unfamiliar sights and sounds. Using a calming tone while speaking at a developmental level the child can comprehend can decrease anxiety and most likely increase cooperation. Allowing parents to be at the bedside is vital for all children, but most especially for these children. Moving children with musculoskeletal disorders can best be accomplished with slow, deliberate motions so as not to frighten the child. The child’s caregivers are the best resource when determining the most appropriate methods for communicating with or moving a special needs child.

### SPECIFIC DISORDERS

#### Airway/Pulmonary Conditions

**Tracheomalacia**

Tracheomalacia is a condition of abnormally weak tracheal walls due to the loss of supporting cartilage and structural integrity. This frequently causes collapse of the trachea on inspiration. Tracheal collapse is most prominent during times of increased airflow, such as when the infant is coughing, crying, feeding, or has an upper respiratory infection.

There are three causes of tracheomalacia: (1) congenital or intrinsic tracheal anomaly (occurring within the trachea), which may be associated with a tracheoesophageal fistula (a patent connection between the trachea and esophagus); (2) extrinsic defects (occurring outside the trachea) such as abnormal development of the vasculature around the trachea that may create a ring, which places pressure on the trachea and interferes with airflow; and (3) acquired malacia, which occurs in children with prolonged intubation or chronic tracheal infections.

Medical management for tracheomalacia consists of symptomatic treatment. A child may experience respiratory compromise with simple viral infections. Racemic epinephrine may decrease swelling of the upper airway under these circumstances. It is prudent to observe these children in the hospital until they are no longer compromised. For children with severe tracheomalacia, a stent or rigid piece of cartilage may be surgically placed in the collapsed area of the trachea to establish permanent patency. Infants with vascular rings may have constricting vessels surgically divided and reattached to surrounding structures in order to release the pressure on the trachea. In rare instances, tracheostomies are placed in order to provide a patent airway until the child’s airway grows and strengthens. Unfortunately, infants often outgrow tracheomalacia.

Regardless of the underlying cause, infants and children with tracheomalacia who are in respiratory distress present with similar signs and symptoms, including cough, prolonged expiratory phase, stridor, accessory muscle use, and hypoxia.

**Bronchopulmonary Dysplasia**

Bronchopulmonary dysplasia (BPD) is a chronic lung disease occurring in infants, which is characterized by stiff lungs and chronic exacerbations. BPD is a worldwide problem with 5000 to 10,000 new cases reported each year and ranking with cystic fibrosis and asthma as the most common chronic lung disease in infants.

BPD develops primarily in low-birth-weight infants who have respiratory distress syndrome (RDS), a lung disease common in premature babies. Babies born prior to 32 weeks’ gestation may not have enough surfactant to keep their alveoli open. However, BPD development is not limited to RDS survivors. BPD may result from alveolar damage caused by other lung diseases, exposure to prolonged high oxygen concentrations, or use of mechanical ventilation after birth (due to conditions such as neonatal pulmonary hypertension, pneumonia, or other infections or trauma to the lungs), all of which can cause harmful chemical reactions in the lungs.

A combination of fewer air sacks and a lack of surfactant can result in abnormally stiff lungs. This increases the work of breathing for affected infants who can quickly become fatigued. As the child progressively weakens, carbon dioxide builds up in the lungs and blood. Respiratory infections can also worsen the inflammatory response in the lungs, leading to more fluid in the lungs and bronchospasm. Other emergencies directly related to BPD include pulmonary edema, aspiration of food or stomach contents into the lungs, and apnea. Signs and symptoms of BPD can vary in severity depending on the infant’s lung maturity. They may include tachypnea, retractions, paradoxical respirations, abnormal posturing, and wheezing.

BPD causes the most difficulties during the first year of life, which is when most deaths from this disorder occur. Problems after the first year become increasingly uncommon. The most common long-term lung complication of BPD is asthma, which occurs in approximately half of patients. Other less common complications include apnea during infancy, gastroesophageal reflux, pulmonary hypertension, high blood pressure, pulmonary edema, aspiration, subglottic stenosis, and tracheomalacia. Infants who have BPD are at risk for frequent hospitalizations because of their borderline respiratory reserve, hyperactive airway, and increased susceptibility to respiratory infection.

Treatment for BPD involves symptomatic relief. Home management may include oxygen, bronchodilators, corticosteroids, diuretics, antibiotics and, in rare cases, ventilator support through a tracheostomy.

**Tracheostomy Tubes**

Tracheostomy tubes are placed to facilitate mechanical ventilation, provide a bypass of the upper airway, or keep the airways clear of secretions. The more common conditions for which tracheostomy tubes are placed include tracheal stenosis, tracheomalacia, certain craniofacial anomalies, bronchopulmonary dysplasia, muscular dystrophy, spinal cord injury, and traumatic brain injury.

Because the tubes are available from several manufacturers, their sizing and markings vary. Common brands include Shiley, Bivona, Hollinger, Portex, and Berdeean. Typically, the sizes are marked on the packaging and on the flange, or wings, of each tube. They range in size from 00 for newborns to 7.0 for older adolescents. The inner and outer diameter ranges are provided so that comparisons between brands can be made. They range from 2.5 mm for infants to 10.0 mm for adolescents and adults. This information is helpful for emergency personnel when replacing a tracheostomy tube or when choosing an endotracheal tube for oral intubation or use through a stoma. The inner diameter of a tracheostomy tube should be used to choose the endotracheal tube size for insertion through a stoma. Tracheostomy tubes also come in various lengths.
Neonatal tubes are shorter than pediatric tubes, although the inner diameters may be the same.

There are several types of tracheostomy tubes and attachments: single-cannula tubes (Fig. 185-1), double-cannula tubes (Fig. 185-2), cuffed tubes (Fig. 185-3), and fenestrated tubes (Fig. 185-4). Neonates, infants, and young children use single-cannula tracheostomy tubes. As a child’s trachea gets larger, a double-cannula tube can be used. This contains an outer tube that stays in the stoma and an inner tube that is removable for cleaning and pulmonary toilet. Tracheostomy tubes for older children and adolescents have an inflatable cuff to keep the tube in place and to prevent air leaks. Fenestrated tubes have a hole in the cephalic portion of the tube that redirects air into the upper airway to allow the child to speak and breathe through the nose and mouth. This is facilitated by a decannulation plug that is attached to the opening of the tube.

Attachments to the tracheostomy tube may include a tracheostomy nose, a tracheostomy collar, and a speaker valve. A tracheostomy nose is placed over the external opening of the tracheostomy tube of a non–mechanically ventilated child to provide air filtration and humidification. A tracheostomy collar is used to provide humidified air or supplemental oxygen to the non–mechanically ventilated patient. A speaker valve is an attachment that redirects airflow through the upper airway to facilitate speech.

**Tracheostomy Emergencies**

Children with tracheostomy tubes seek emergency care for three primary reasons: (1) an exacerbation of the underlying pulmonary disease, (2) blockage of the tube by a mucous plug, or (3) equipment failure. Signs and symptoms of respiratory distress include nasal flaring, retractions, increased respiratory rate, decreased breath sounds, decreased oxygen saturation, cyanosis, wheezing, rales, and increased secretions.

Sudden onset of respiratory distress may suggest a mucous plug or equipment failure rather than a pulmonary infection, which is usually heralded by a more progressive deterioration of respiratory status and fever. Airway assessment should include inspection of the tracheostomy tube for patency.

For the child experiencing an exacerbation of pulmonary disease, infection and reactive airway disease are the most
likely possibilities. Acute treatment for wheezing includes administration of a bronchodilator by nebulizer through the tracheostomy or in-line with the ventilator in a mechanically ventilated child. In a child with a fever, infection should be considered, chest radiography and tracheostomy cultures obtained, and antibiotic coverage provided. The need for hospitalization is determined by a combination of factors including age, medical history, severity of illness, and diagnosis. Medical personnel should consider transporting medically complex children to their home hospital for care by physicians who know them best.

For the child with sudden onset of respiratory distress, suctioning the tracheostomy tube may be helpful. Approximately 2 to 3 mL of normal saline should be instilled prior to suctioning. If suctioning two to three times does not relieve the obstruction or respiratory distress, then the medical provider should change the tracheostomy tube because there may be a thick mucous plug obstructing airflow through the tube. As with any procedure, the practitioner should be prepared and have the appropriate supplies available; an endotracheal tube can be used as a substitute in the appropriate size if a tracheostomy tube is not available. Also, parents and caregivers often have spare equipment in their “go” bags that can be used (for troubleshooting, see Table 185-1).

**Apnea**

Apnea in infants and young children is defined as a cessation in breathing for more than 20 seconds or associated with a change in color, limpness, altered mental status, or bradycardia. Apnea occurs more frequently in infants born prematurely and generally reflects immature neurologic and respiratory control mechanisms. These pauses in respiration may be due to central apnea, which is the result of an absence of a neurologic signal to the respiratory muscles. Underlying causes include encephalitis, brainstem infarction or tumor, neuromuscular disorders such as muscular dystrophy, or thoracic restrictive disorders such as kyphoscoliosis. These children are

Adapted from Adirim T, Smith E: Special Children’s Outreach and Prehospital Education. London, Jones and Bartlett, 2005.
discharged home from the hospital on an apnea monitor. Apnea monitor alarms often result in ED visits. The apnea monitor should be transported with the child to the hospital. Most monitors contain a computer chip that records information that can be downloaded into a computer at the home hospital to determine the origin of the monitor alarms (high or low heart rate, apnea, or artifact). This diagnostic procedure can be expedited when the child is transported to his or her home hospital.

The most common type of childhood apnea is obstructive apnea, which is caused by an occlusion in the upper airway at the oropharyngeal level or by gastroesophageal reflux disease (GERD). GERD occurs when the lower esophageal sphincter opens, causing stomach contents to pass into the esophagus during or after a meal. Younger children tend to outgrow this condition. Those who continue to be symptomatic can experience complications such as a chronic cough, recurrent pneumonia, difficulty swallowing, recurrent vomiting, and weight loss. Symptoms can often be controlled with positioning, diet, medications, and, in rare circumstances, surgery.

Mixed apnea is central apnea that is followed by an obstructive apnea event. Obstructive sleep apnea may be managed by providing oxygen during sleep or through nasal continuous positive airway pressure (CPAP), which may be delivered through a nose mask or tracheostomy. Central apnea is managed with supplemental oxygen and CPAP but also responds to medications that stimulate the respiratory system or mechanical ventilation.

**Home Mechanical Ventilation**

Many children with tracheostomies are also mechanically ventilated. Indications for mechanical ventilation include severe lung disease and abnormal respiratory drive either from central causes or secondary to paralysis. Some children are dependent on ventilators 24 hours a day, some while asleep, and others for part of the day.

There are two types of ventilators: pressure-cycled ventilators and volume ventilators. Pressure-cycled ventilators tend to be used in infants. They are set to deliver a given pressure with each breath. Volume ventilators give a tidal volume with each breath. There are two common modes of ventilations: intermittent mandatory ventilation (IMV) and controlled mechanical ventilation (CMV). IMV mode delivers a mechanical breath between the patient’s own respirations to ensure that the patient achieves a certain number of breaths per minute. The ventilator synchronizes its breaths with the patient’s breaths. On the other hand, with CMV, the ventilator is set to deliver a certain number of breaths per minute whether or not the patient can breathe without assistance. Some ventilators have an assist control mode in which the ventilator gives a breath at the same time the patient takes a breath to augment the patient’s effort.

There are five types of home ventilator alarms: (1) low pressure/apnea, (2) low power, (3) high pressure, (4) setting error, and (5) power switchover. The causes of a low-pressure alarm include a loose or disconnected circuit, a leak in the circuit, and a leak around the tracheostomy site. The low-power alarm indicates the internal battery is near completion and the ventilator will need to be plugged into an electrical outlet. A high-pressure alarm indicates the internal battery is near completion and the ventilator will need to be plugged into an electrical outlet. A high-pressure alarm indicates the setting has been improperly adjusted. Under these circumstances the patient should be manually ventilated until the ventilator can be set properly. The power-switchover alarm sounds whenever the ventilator switches from AC power to battery power. When this happens, check to ensure that the battery is powering the unit before pressing the “alarm silent” button.

Possible causes of respiratory distress in a ventilator-dependent child include airway obstruction (e.g., obstructed tracheostomy tube), an obstruction or leak in the ventilator tubing, problems with the oxygen supply, equipment failure involving the ventilator, or a medical condition. If a ventilator-dependent child is found to be in respiratory distress and the cause is not easily determined, the child should be taken off the ventilator promptly and ventilated with a manual resuscitator (bag device). Manually ventilating the child can help determine if the equipment has failed or a medical condition is responsible.

**Congenital Cardiac Conditions**

Congenital cardiovascular defects are the most common forms of malformations in newborns, with a reported incidence ranging from 4 per 1000 to 50 per 1000 live births (see Chapter 169). The diagnosis is established within the first year of life in 40% of patients with congenital heart disease (CHD). Left untreated, the condition proves fatal in most cases before age 20. Cardiovascular defects are considered to be the leading cause of neonatal death due to congenital abnormalities. However, from 1979 to 1997 mortality due to CHD declined by 40% due to early diagnosis, improved surgical treatment, and advances in medical technology.

When an infant is born with a severe cardiac anomaly, interventions are primarily directed toward maximizing home health care until definitive surgery can be performed, although some defects cannot be surgically corrected.

Complex CHD is divided into acyanotic and cyanotic lesions.

**Acyanotic Lesions**

Acyanotic lesions account for most cases of CHD. With acyanotic defects, there is no mixing of desaturated (poorly oxygenated venous) blood in the systemic arterial circulation. The defects are associated with left-to-right shunts and obstruction to the ventricular outflow. Left-to-right shunts cause oxygenated blood from the left side of the heart to mix with deoxygenated blood from the right side of the heart. Long-term left-to-right shunting of blood leads to complications, and therefore these infants should receive surgical repair as soon as possible. Some of the more common acyanotic cardiac lesions involve a defect in the septum. These include atrial septal defects (ASDs), ventricular septal defects (VSDs), and atrioventricular canal defects (endocardial cushion defect or atrioventricular septal defect). The atrioventricular canal defects are more serious and almost always require surgical repair. VSDs in the muscular part of the septum often close on their own and only need to be repaired surgically if they are large and cause serious symptoms. Small ASDs have a very high rate of spontaneous closure, so surgical correction is delayed until the child is 3 to 4 years of age. However, if the defect is large and untreated, the patient may present with congestive heart failure or pulmonary hypertension as a result of volume overload. Typical later findings on cardiac exam include a fixed, split S2 sound.

**Obstructive Lesions**

Obstructive lesions obstruct ventricular outflow. Some of these include pulmonary stenosis, aortic stenosis, and coarctation of the aorta. Infants with pulmonary stenosis have mild defects that are usually asymptomatic. Signs and symptoms of aortic
Cyanotic Lesions

Cyanotic defects are less common congenital cardiac conditions. Blood from the arteries and the veins mixes in the heart, causing baseline low blood oxygen levels. (Normal pulse oximetry readings can range from the 60s to the low 90s in unrepaired cyanotic defects.) The degree of cyanosis may vary with age, activity, and the severity of defect. In many instances, cyanosis is common and can develop quickly because of decreased ventilatory reserve. This type of heart disease can result in a true life-threatening emergency since circulatory collapse is imminent after the development of acidosis. Cyanotic cardiac defects include hypoplastic left heart syndrome, tetralogy of Fallot, transposition of the great arteries (TGA) (Fig. 185-5), tricuspid atresia, pulmonary atresia, and truncus arteriosus. The most important management issues for these children are prevention and treatment of heart failure and acidosis and maintenance of oxygen saturation in the child’s “normal” range, which may be below 90%.

Children with complex CHD are often small for age, and some may be developmentally delayed. When a child with complex CHD presents to the ED for treatment, asking the caregivers about the child’s usual appearance, usual oxygen saturation, and developmental age is extremely helpful in managing the child’s care. It is also useful to know which cardiac procedures the child has undergone to anticipate complications. Table 185-2 is a summary of the more common procedures and their complications.

Neurologic Conditions: Cerebral Palsy and Seizures

Cerebral Palsy

Cerebral palsy (CP) is the leading cause of childhood disability. CP is a group of disorders affecting the development of movement that is attributed to nonprogressive disturbances that occur in the developing fetal or infant brain. The motor disorders are often accompanied by one or more of the following: disturbances of sensation, cognition, communication, perception, or behavior or a seizure disorder. Premature birth is the most common associated historical factor, and prenatal maternal infection and multiple pregnancies have also been associated with CP.

CP is classified based on the type of movement disorder and the area of the body involved: spastic, athetoid, ataxic, mixed and hemiplegia, diplegia, or quadriplegia. The most common form, spasticity, is defined as a velocity-dependent resistance to stretch. When the extremities of a child with the spastic form of CP are stretched beyond their range of motion, the muscles contract and increase resistance. Clonus, an extensor plantar response and persistent primitive reflexes, is characteristic. Since CP is a movement disorder, gross motor skills are delayed. There is a lack of coordination and differential strength and tone in the musculature of the child. Treatment is focused on managing spasticity. Some of the treatments include daily range-of-motion exercises, casting, and splinting. Some children may take oral medications (baclofen, diazepam, and clonidine) to improve muscle spasticity or to decrease the drooling that is evident in 10% of children with CP, caused by poor oromotor control combined with decreased sensation and poor head control.

Intrathecal Baclofen Pump. Some children with CP are now treated with baclofen pumps inserted directly into the thecal sac surrounding the spinal cord. Baclofen is directly infused into this space by a small pump via continuous infusion. Baclofen acts by binding to receptors in the spinal cord, thereby inhibiting spinal reflexes. Complications include overdose when the pump is filled incorrectly or programming is inaccurate. Overdose can lead to respiratory depression and death. Some less serious side effects of the medication include drowsiness, dizziness, hypotension, headache, and nausea. If presented with a comatose child with CP on a baclofen pump, the physician must maintain the child’s airway, breathing, and circulation until the pump is urgently stopped with a specialized device. If this device is not readily available, then emptying the reservoir with a 22-gauge needle is an alternative treatment. This can be done by locating the pump in the abdominal wall and inserting the needle in the center of it. Another complication is medication withdrawal due to pump failure, which is usually the result of tube obstruction or faulty

<th>DESCription</th>
<th>MOST COMMON COMPLICATIONS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Modified BT shunt</td>
<td>HLHS</td>
<td>Palliative procedure to augment pulmonary blood flow; used prior to complete repair of lesions with single ventricle physiology.</td>
<td>Thrombosis of the shunt. Diagnosis is made by echocardiography or CT angiography. Another rare complication is a seroma adjacent to the shunt causing airway compromise or cardiac tamponade.</td>
</tr>
<tr>
<td>BDG shunt</td>
<td>HLHS</td>
<td>Palliative procedure to shunt systemic venous blood to pulmonary artery; originally created to palliate tricuspid atresia and other underdeveloped right heart lesions.</td>
<td>Pulmonary arteriovenous fistulas, which cause ineffective gas exchange.</td>
</tr>
<tr>
<td>Modified Fontan and Hemi-Fontan</td>
<td>Ticuspid atresia HLHS</td>
<td>Creates a circulation where the systemic venous blood enters the pulmonary circulation directly, bypassing the right ventricle.</td>
<td>Pulmonary arteriovenous malformations, protein-losing enteropathy, elevated systemic or right atrial pressures, thrombosis in the right side of the heart and the Fontan conduit, pulmonary effusions, arrhythmias, progressive exercise intolerance, anastomotic stenosis, and hepatomegaly.</td>
</tr>
<tr>
<td>Norwood procedure</td>
<td>HLHS</td>
<td>The purpose is to create a systemic circuit in children with one ventricle physiology; this is done in three stages because pulmonary vascular resistance is high in newborns.</td>
<td>This procedure is done in three stages to avoid complications and to allow child to grow.</td>
</tr>
<tr>
<td>Norwood, stage 1</td>
<td>HLHS</td>
<td>This is done during the first days after birth. This establishes a connection between the right ventricle and the systemic arterial system, creates sufficient pulmonary venous return, and establishes pulmonary blood flow with a systemic to pulmonary shunt such as a modified BT shunt.</td>
<td>Thrombosis of the shunt.</td>
</tr>
<tr>
<td>Norwood, stage 2</td>
<td>HLHS</td>
<td>This procedure is usually done when the pulmonary vascular resistance has decreased to normal at about 3–6 months of age. A cavopulmonary shunt is created; either a BDG or hemi-Fontan is performed to accomplish this. The BT shunt is removed during this stage.</td>
<td>Pulmonary arteriovenous fistulas.</td>
</tr>
<tr>
<td>Norwood, stage 3</td>
<td>HLHS</td>
<td>This is the modified Fontan procedure. This stage completes the separation of the pulmonary and systemic circulations.</td>
<td>Pulmonary effusions, pericardial effusions, ascites, hepatomegaly or SVC syndrome, protein-losing enteropathy, and cardiac failure.</td>
</tr>
<tr>
<td>Rastelli</td>
<td>TGA</td>
<td>The aorta and the coronary arteries arise from the RV instead of the LV, and the PA emanates from the LV, which creates a parallel circulation. The definitive procedure, the Jatene arterial switch, is performed within the first weeks of life. This procedure involves transaction of the 2 arteries, switching them to their respective ventricles, and also moves the coronary arteries as well.</td>
<td>Dilatation of the neoaortic root (AV regurgitation is rarely seen); risk of coronary artery occlusion or stenosis. If the definitive surgery correction cannot be done in the first days of life, then a first procedure may be done at 1–3 days of life if there is no connection between the 2 circulations (e.g., VSD)—the Rashkind procedure where a balloon catheter creates a hole in the atrial septum.</td>
</tr>
<tr>
<td>Rastelli</td>
<td>TGA with VSD and LVOT obstruction Pulmonary atresia with VSD Double outlet right ventricle with PS or PA</td>
<td>Alternative procedure for patients who cannot undergo arterial switch. This procedure bypasses the LVOT. First the LVOT is closed off, a tunnel is created between the LV and into the aorta, the VSD is enlarged, and the RV to the PA flow is augmented by a pulmonary allograft.</td>
<td>LVOT and right-sided conduit obstruction; highlate mortality.</td>

Seizures

Seizure disorders affect approximately 10% of children who are disabled, compared with only 0.5% of healthy children. Seizures are divided into multiple categories. Children with seizure activity often have normal intelligence, and their seizures can be well controlled by anticonvulsant medication. “Breakthrough” seizures generally occur as a result of toxic or subtherapeutic blood levels of seizure medication for a variety of reasons. These include but are not limited to poor absorption of their medication secondary to a gastrointestinal illness, missing one or more doses of anticonvulsant medication, medication dosages not being appropriately adjusted for the child’s growth, or a lowered seizure threshold such as from an illness or accidental multidosing of a patient’s medication. For patients with multiple abnormalities, seizure activity is generally more severe and is more difficult to control with anticonvulsant medications.

Children with CP or other brain abnormalities are more likely to experience status epilepticus. Status epilepticus is a condition of generalized convulsions in adults and older children (>5 years old) for 5 minutes continuously or two or more discrete seizures without full recovery of consciousness. Early intervention is important. Treatment initially includes benzodiazepines, which are often effective; if two doses of a benzodiazepine are not effective, subsequent doses are not likely to work, and phenytoin (Dilantin) or fosphenytoin (Cerebyx) is considered the next line of medication. (See Chapter 173 for a complete discussion of the management of intractable epilepsy.)

Vagal Nerve Stimulators

Vagal nerve stimulators (VNS) are implantable devices used to prevent seizures. Intractable epilepsy affects approximately 20 to 30% of patients with seizures. Newer antiepileptic drugs and surgical procedures decrease seizure frequency in a significant number of patients. Even among this group, up to 10% continue to have disabling seizures. For these patients, VNS provides hope for better seizure control.

The VNS is an implantable device that looks like a pacemaker. It is implanted by a neurosurgeon just under the skin in the chest. In the small number of children who have had VNS placed, most have seen a reduction in seizure frequency of 50%. How the VNS works on the brain is not known. The vagus nerve is a peripheral nerve that leads directly to the brain and it is there that the VNS has an effect.
The VNS is programmed to provide baseline intermittent stimulation of the left vagus nerve. Although the VNS system delivers stimulation automatically in regular pulses all the time, a magnet can be used to deliver extra electronic stimulation in between cycles. The patient or caregiver activates the device by placing a handheld magnet over the device implanted in the chest.22 Patients who can sense that they are about to experience a seizure can activate the VNS themselves by passing the magnet over the device. Out-of-hospital providers who encounter a seizing patient with a VNS should assist the caregiver with its activation or seek advice from medical control. Children with VNS devices should otherwise be treated as other seizing patient, with careful attention to airway, breathing, and circulation. A magnet can also be used to stop the stimulation by holding the magnet over the device. Sometimes the patient may want to shut the stimulation off. Some of these include when eating if the stimulation causes problems with swallowing, when the patient plans to speak or sing in public as the stimulation can change one’s voice, and if the stimulation causes discomfort.22,23

Myelomeningocele and Hydrocephalus

Myelomeningocele (or spina bifida) refers to a gap in the vertebral arches. The most common types of spina bifida are spina bifida occulta, the milder form, and spina bifida associated with malformation of the spine and attachment of the sac—a condition known as myelomeningocele. The rate of spina bifida in the United States has decreased markedly since the introduction of folic acid to the diets of women of childbearing age.

Clinical presentation depends on the level of the defect. The condition results in partial or complete paralysis and loss of sensory function (not always symmetrical) with motor loss. In addition, the child may present with loss of bladder or bowel control, cognitive impairments, visual deficits, and seizure disorders. Bladder and bowel dysfunction is very common among children with spina bifida. In such cases, there is incomplete emptying of the bladder, predisposing the child to urinary tract infections. Management of such cases requires emptying of the bladder by urinary catheterization several times a day. Hydrocephalus associated with Chiari malformation (displacement of the brainstem and part of cerebellum downward through the skull) occurs in greater than 68% of children with spina bifida.24 One should always assume that children with spina bifida are allergic to latex.25

Ventriculoperitoneal Shunts

Ventriculoperitoneal (VP) shunts are catheters that are inserted into the ventricles within the brain and then threaded under the skin from the skull to the peritoneum where excess cerebrospinal fluid (CSF) is drained (Fig. 185-6). Hydrocephalus occurs when an obstruction occurs somewhere in the CSF circulation system. If the obstruction occurs beyond the lateral ventricles, then they enlarge with CSF, increasing intracranial pressure. Hydrocephalus can be seen in formerly premature infants who sustained an intracranial hemorrhage during the neonatal period, in children with brain tumors, and post-traumatically. Also, children with spina bifida (myelomeningocele) often have hydrocephalus if they have an Arnold-Chiari malformation that obstructs CSF flow.

Within the first 3 postoperative months, although rare, a child with a VP shunt can develop an infection of the shunt track. Symptoms include fever, ill appearance, erythema over the shunt site or tubing, tenderness over the tubing, abdominal pain and tenderness, vomiting, and altered mental status. If a VP shunt infection is suggested, CSF should be drawn from the shunt by a neurosurgeon and sent for cell count and culture. Broad-spectrum antibiotics should be administered pending cell count and culture results; however, likely organisms include Staphylococcus epidermidis, Staphylococcus aureus, and, rarely, Haemophilus influenzae. Neurosurgeons should manage all shunt infections.

Peritonitis is another complication of VP shunts. The tip of the shunt empties into the peritoneal cavity and as a foreign body can serve as a nidus for infection. Signs and symptoms include fever, vomiting, abdominal pain and tenderness, and abdominal distention. Management is similar to that for VP shunt infections and should include diagnostic lab work, broad-spectrum antibiotics, and consultation with the neurosurgeon.

The more common complication of a VP shunt is shunt obstruction or malfunction. This can occur with an increase in protein in the CSF that causes a blockage in the tubing or as a result of a mechanical disruption in the shunt tubing. This can cause a buildup of CSF in the ventricles and an increase in intracranial pressure. Signs and symptoms include headache, nausea, vomiting, irritability, altered mental status, ataxia, change in vital signs, and a bulging fontanel in an infant. Initial management should include elevating the child’s head and managing the patient’s airway, breathing, and circulation. Stable patients should have head computed tomography performed, and a neurosurgeon should be consulted as soon as possible. The definitive treatment is surgical shunt revision.26

Gastrostomy Tubes

Gastrostomy tubes are placed in children who need long-term nutritional supplementation or cannot take food by mouth. There are many conditions that necessitate placement of an artificial feeding tube including severe developmental delay, coma, short bowel syndrome, swallowing difficulties, burns to mouth and esophagus, failure to thrive, and chronic diseases that affect nutrition such as cystic fibrosis.

Gastrostomy tubes are surgically or endoscopically placed feeding catheters. These tubes include gastrostomy tubes...
(G tubes), jejunostomy tubes (J tubes), and percutaneous endoscopic gastrostomy tubes (PEGs or buttons). J tubes are placed in children with GERD. The tube is placed in the stomach and then passed through the junction between the stomach and jejunum, bypassing the stomach. PEGs are placed by gastroenterologists either at the bedside or in the outpatient procedure area.

There are three potential gastrostomy tube emergencies. (1) The tube can leak gastric contents, (2) become obstructed, or (3) come completely out. When presented with a child who has any of these problems, assessment of hydration status is important, especially in those children who are totally dependent on their feeding tubes for hydration and nutrition. One should inquire about prescribed medications and whether any doses were missed.

In children experiencing leakage around the catheter, management focuses on delineating and fixing the cause of the leak. Possible causes of leakage include balloon deflation, coughing, constipation, bowel obstruction, and seizure. Addressing the cause may solve the problem; otherwise, consultation with the subspecialty service that manages the child's tube may be necessary (Table 185-3).

Sometimes the child’s G tube becomes clogged with medication or food. Obstructed tubes can be cleared with either Coca-Cola or a proteolytic enzyme solution; otherwise, they need to be replaced.

G tubes that have fallen completely out of the patient need to be replaced as soon as possible, so the stoma does not constrict and make replacement difficult. Gastrostomy-jejunostomy tube placement is more problematic because after placing a tube in the stomach, passing the tube to the jejunum is usually done under fluoroscopy by a radiologist familiar with this procedure. For G tube replacement, the physician should ask when the tube was first inserted. For tubes that are less than 3 months old, consultation with the person or service that performed the procedure is necessary because the track may not yet be fully formed and insertion by a practitioner not adept at replacing these tubes may create a false track.

When performing the reinsertion procedure, a similar size gastrostomy tube should be used. Parents often have an extra tube with them. If cases when the ED does not have access to G tubes (the Mic-Key type of tube is easiest to use), using a Foley catheter to temporarily keep the stoma open is acceptable until definitive placement can occur. Once the G tube is replaced, tube placement can be confirmed by instilling a small amount of diatrizoate meglumine (Gastrograffin) dye into the tube (15–30 mL) and obtaining two radiographic views to observe the tube and dye in the stomach. Central Venous Catheters

Central venous catheters, or central lines, are used to deliver medications, blood products, and nutrition directly into a central vein. There are a number of circumstances when a child would need a central venous line, including children with cancer who need chemotherapy, children with sickle cell disease who need frequent transfusions, children with infections who need long-term antibiotic therapy, and various conditions in which nutritional supplementation is needed, such as in short bowel syndrome.

There are three types of catheters. Peripherally inserted central venous catheters (PICC) are long catheters inserted into the cephalic vein via the antecubital fossa. The catheter is advanced into the subclavian vein. These tubes are placed in children who need temporary venous access, such as for antibiotic therapy. These tubes can be placed by nonsurgeons. Potential complications include infection, obstruction, and easy dislodgement because they are not sutured in place (Table 185-4).

Tunneled central venous catheters are placed surgically. They are inserted directly into a central vein, most commonly the subclavian, cephalic, or external jugular. There are three
common types: Broviac, Hickman, and Groshong. The first two are most commonly used in children. The distal ends rest outside the chest and can have one to three ports. Implanted vascular access ports (Port-A-Cath, PAS Port, and Med-A-Ports) are also common in children. The insertion sites and method are the same as for the tunneled central venous catheters. The distal end of the catheter consists of a reservoir that is covered with a self-healing rubber septum. This reservoir rests subcutaneously, and a special needle is needed to access this line. The advantages of the implanted vascular ports are that they only need to be flushed with heparin once a month and after each access, as opposed to daily heparin flushes, and they are hidden and so may be more acceptable to older children for whom body image is more of an issue.

Circumstances where a child with a central line presents for emergency treatment include damage to the catheter, air embolus, catheter dislodgement, and fever. Catheters that are damaged should be clamped proximal to the break with a hemostat. With catheters that are dislodged, the practitioner should apply direct pressure at the entry site to stop or prevent bleeding. This is a potential life-threatening emergency. The child should be brought to a facility that can repair or replace the catheter. Air emboli in the tubing can cause sudden onset of respiratory distress, chest pain, and altered mental status. If an embolus is suggested in a child with a central line, the child should be placed on his or her left side and given oxygen. Peripheral IV placement should be considered.

Fever is a common problem in children with central lines. The line is a foreign body that can act as a direct conduit for microorganisms, a situation that is especially problematic for immunocompromised children who can easily develop sepsis. Treatment of these children should include obtaining blood samples for complete blood count and cultures and administering broad-spectrum antibiotics until culture results are known. Neutropenic patients (absolute neutrophil count <500) should be admitted to the hospital for IV antibiotics pending blood culture results. If the febrile child with a central line is not immune suppressed and appears well, discharging the child home with appropriate follow-up is appropriate. In borderline cases, consultation with the child’s physician can aid in making disposition decisions.

### KEY CONCEPTS

- CSHCN are frequent users of the health care system. Parents and caregivers often know their children’s issues very well. They may have information cards or notebooks describing their child’s conditions and equipment and listing medications, or the child may be wearing medical jewelry. Listen to the caregivers when treating CSHCN.
- CSHCN may be physically smaller than children of the same chronologic age, may have vital signs outside the range of normal for age, and may also be developmentally delayed. Ask caregivers what is normal for their child.
- Most children with special health care needs suffer the same typical diseases as their normal counterparts. Treatment of CSHCN should begin with assessment of the child followed by assessment of medical equipment. When in doubt regarding the best course of action, maintain the child’s ABCs while seeking consultation from the child’s pediatrician or surgeon.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

The assessment and treatment of pain are parts of the chief complaint in up to 70% of patients in the emergency department (ED). Pain can be present in a wide variety of physical and psychosocial situations but is almost always present in the setting of tissue injury. Pain can therefore be assumed to be present in patients with physically apparent disease or injury, even in those who cannot effectively communicate their condition.

A wide variety of options are available for the treatment of pain. Despite being easy to identify and having effective treatments available, the treatment of pain is often extremely difficult to do effectively in the ED and is often one of the most challenging and frustrating aspects of the practice of emergency medicine.

Patients’ perceptions of their ED care are highly influenced by pain treatment, and satisfaction with emergency care often depends on the techniques and timeliness of analgesia as well as the discharge plans for pain relief. In every interaction with a patient in pain, a balance must be struck between relieving the patient’s suffering in the ED and during the subsequent recovery and in appropriately diagnosing and treating the underlying medical condition.

Other than the obvious fact that relieving pain is associated with less suffering for a patient, a growing body of evidence supports the importance of effective pain management as a central aspect of the treatment of disease. Acutely, unrelieved pain is associated with a variety of potential negative physiologic outcomes, including increases in sympathetic outflow, peripheral vascular resistance, myocardial oxygen consumption, and the production of carbon dioxide; hypercoagulability; and decreases in gastric motility and immune function. Poorly treated acute pain can aid in the development of chronic pain syndromes and vegetative symptoms, as well as increasing the need for pain treatment during the recovery period. Pain during subsequent procedures may actually increase if successful analgesia was not provided during previous procedures. It is likely that a patient’s experience of pain increases the ability to perceive pain from similar stimuli in the future, leading to increased pain in patients who receive inadequate analgesia during future painful events.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires hospitals to develop comprehensive programs for the measurement, treatment, documentation, and institution of quality improvement efforts related to acute pain management. These requirements were established at the same time that the treatment of pain in the ED was undergoing increased scrutiny through clinical research. The improvement in pain management in the last decade may be due to both factors.

There are many ways to treat pain, and very few single approaches are clearly superior to all other options. Uncontrolled pain should be considered a medical emergency with the estimated degree of pain playing a role in the determination of a patient’s overall acuity for triage. Pain estimations, using both provider- and patient-derived scales, should be obtained and recorded for patients as frequently as any vital sign. Important terms relating to analgesic practices are listed in Box 186-1.

PATHOPHYSIOLOGY

Pain can be generally described as nociceptive or neuropathic. Nociceptive pain results from the activation of sensory neurons that signal pain (nociceptors) in response to noxious stimuli. Neuropathic pain results from signal processing changes in the central nervous system (CNS). It is usually described as burning, tingling, or shooting pain and includes neuropathies and deafferentation. Both types of pain involve both peripheral and central sensitization involving a complex array of mediators to sensitize peripheral nociceptors and perpetuate thalamic signals. An overview of the physiologic process of pain is in Figure 186-1. At each level in the physiologic process of pain production or transmission, interventions are available to alter the process.

Pain Conduction Pathways

The perception of pain can be divided into four separate processes, the pain detection system (transduction), the pain transmission system, the pain modulation system, and the pain expression system (perception) (see Fig. 186-1). The transduction of painful sensory input is initiated by activation of the nociceptors, with subsequent depolarization of their axons. The axons relay information (afferent input) to their cell bodies located in the dorsal root ganglion just lateral to the spinal cord. Central dendrites of these first-order neurons synapse in the dorsal horn, where sensory input is modulated. The signal then travels through the spinothalamic tracts and posterior columns to synapse in the reticular system and the thalamus. From there the signal is projected to the cerebral cortex.
Definitions of Terms Related to Analgesia

Amnestic—an agent that suppresses the formation of memories
Local anesthesia—creating an area of insensibility to pain by the injection of a local anesthetic agent
Analgesia—relief from pain
Hypnotic—an agent that promotes the onset of sleep
Narcotic—a term with legal implications describing opioid agents together with various central nervous system depressant drugs of abuse
Nociceptor—a receptor that is sensitive and responsible for transmitting pain stimuli
Noxious stimulus—a stimulus that is damaging or potentially damaging and results in sensation of pain
Opiate—a naturally occurring derivative of opium alkaloid that binds opiate receptors and produces effects similar to those of the endogenous endorphins
Opioid—a naturally occurring (includes all opiates) or semi-synthetic derivative of opium alkaloid that binds opiate receptors and produces effects similar to those of the endogenous endorphins
Pain—an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage
Procedural sedation—pharmacologically producing a state of sedation or dissociation with amnesia for pain control during a painful procedure (see Chapter 187)
Sedative—an agent that decreases a patient’s awareness

Information Transmission

Peripheral Nerve Fibers

All sensory neurons are composed of a cell body, which is located in the dorsal root ganglia, and a receptor located within a given dermatome (cutaneous input), sclerotome (input from bones), or myotome (input from muscle), connected by an axon. The discrete areas covered by each nerve provide a sensory map of the body surface. Table 186-1 is a classification system of peripheral nerve fibers that describes the roles of the different fibers. A-δ and C type fibers are responsible for the transmission of pain. A-δ fibers transmit sharp initial pain that persists as long as the inducing stimuli, and C fibers transmit dull, aching, or burning pain that persists longer than the initial stimuli. The relative concentration of nerve fiber types varies in different tissues. Muscle C fibers, for example, produce aching, poorly localized pain in response to violent contraction or stretch, ischemia, or inflammation. In joints, afferents respond to noxious movement of the joint, the threshold of which is sensitized by chemicals present during inflammation (accounting for the pain with normal movement associated with arthritis or after an injury). The periosteum has the lowest pain threshold of all the deep tissues and is supplied by both A-δ and C fibers, whereas cortex and marrow have very few nociceptors.

Pain Transmission

Dorsal Horn

The dorsal horn is the gray matter in the posterior aspect of the spinal cord (Fig. 186-2). The dorsal horn acts as an integration system where sensory input is filtered, attenuated, or amplified before being relayed to other spinal segments or the cortex.

The dorsal horn is structured in layers called laminae. Each lamina receives specific types of nerve fibers, and the various laminae are connected by multiple interneurons. The dorsal horn is a processing center for incoming information and is extensively involved in the modulation of nociceptive input. Visceral, muscle, bone, and cutaneous afferents converge here, which probably accounts for the cutaneous allodynia associated with painful visceral, muscular, or bony stimuli. Differ- entiation between innocuous stimuli and nociceptor input occurs due to a higher frequency of discharge from painful stimuli in cells called wide dynamic range neurons (WDRNs) as they receive the input. WDRNs receive modulating input from a variety of chemical (opioids, substance P, or inflammatory factors) and efferent and afferent pathways.

Lamina II has projections to laminae I that influence the WDRNs there, making these laminae the likely primary modulating source on afferent painful impulses.

Laminae V receives A-δ and C fiber input and projects to both the spinothalamic and spinoesencephalic tracts, which account for many of the reflex responses to pain.
Visceral Pain

The quantity and type of stimuli that produces pain varies among visceral structures. The myocardium, for example, is sensitive to ischemia but not mechanical stimulation. The intestines can be cut, crushed, or burned without pain, but traction or distention produces pain. The quality of visceral pain is different from somatic pain. Somatic pain is initially sharp and later becomes burning or throbbing in nature as the pain is transmitted from the peritoneum to the posterior parietal peritoneum, which has the same nerve supply as the overlying myotome and dermatome.

Ascending Tracts Associated with Pain

Fibers carrying pain impulses exit the dorsal horn and ascend the spinal cord to the brain. The predominant pathways for pain conduction are the spinothalamic tract, the spinothalamic tract, and the spinoreticular tract, located in the anterolateral aspect of the spinal cord (Fig. 186-3). The spinothalamic tract is the most important for pain transmission. Lesions in this tract (the anterolateral portion of the spinal cord) cause the loss of pain sensation in the contralateral side below the lesion. The cell bodies of this tract are in laminae I and V of the dorsal horn. Axons cross the midline within two spinal segments of their origin and then ascend the tract. The axons synapse in the ventroposterolateral nucleus of the thalamus and the posteromedial thalamus, where they then project to the cortex. As these tracts ascend, they add fibers to the anteromedial border, producing an organization with sacral segments located dorsolaterally and cervical segments located anteromedially.

The spinoreticular tract ends in synapses in the reticular formation of the medulla, pons, midbrain, and intralaminar thalamic nuclei, which ultimately project to the limbic forebrain. The spinoreticular tract is an important part of the suprasegmental reflex responses to pain and serves as a direct link between the reticular arousal centers and the dorsal horn. Spinothalamic tract fibers synapse in the periaqueductal gray matter and other midbrain nuclei, where they likely activate a system of descending pain inhibitory signals that project from the periaqueductal gray matter.

The dorsal columns of the spinal cord mostly transmit innocuous sensory information but may also play a role in pain through modulation of the spinothalamic tract. In addition to providing discriminatory information to localize pain, sensory input may activate cortical descending pathways that modulate the dorsal horn response to nociceptive input. The spinothalamic tract then provides precise localization of the nociceptive data, whereas the spinoreticular and spinothalamic tract input serves to arouse the body to ongoing tissue damage, activating the neuroendocrine, emotional, and autonomic reflexes associated with pain.

Thalamus

The thalamus receives input from the spinoreticular and spinomesencephalic tracts in the medial and intralaminar nuclei, which project to a wide area of the cortex and the limbic structures.
system. The spinothalamic tract and the periaqueductal gray matter project to the ventroposterolateral and ventroposteromedial nuclei, which also receive input from descending fibers from the somatosensory cortex. It then projects to a wide area of the cortex. Cerebrovascular disease or injury to the thalamus can produce central neuropathic pain syndromes in the absence of its modulating effect on pain.

**Pain Modulation**

Impulses from nociceptors are modulated by descending tracts both peripherally and in the spinal cord. The two primary descending pathways appear to be primarily serotonergic and noradrenergic, and originate in the midbrain (periaqueductal gray matter and locus ceruleus) and medulla (nucleus raphe magnus and nucleus reticularis gigantocellularis). They are transmitted to the spinal cord via the dorsolateral funiculus. Electrical stimulation of this pathway produces analgesia comparable to that produced with opioids. Stimulation of the thalamus can also produce analgesia. Inputs to this system come from the frontal cortex, the limbic system, the hypothalamus, the reticular system, the locus ceruleus, and the spinal cord. Multiple neurotransmitters are involved in these pathways, including serotonin, norpinephrine, and substance P. It is believed that the activation of this system is responsible for effects such as placebo, acupuncture, and TENS units.

**Central Sensitization**

Central sensitization involves the amplification of nociceptive signals. It is mediated by multiple substances such as nitric oxide, glutamate, substance P, aspartate, prostaglandins, leukotrienes, norepinephrine, and serotonin. It can occur in the presence of chronic pain or as the result of damage at any point along the pain transmission system. It is described in the setting of traumatic and degenerative conditions of the spinal cord and brainstem and can be associated with thalamic strokes, multiple sclerosis, Parkinson’s disease, Arnold-Chiari formation, and cervical stenosis.

**Pain Expression**

The transduction, transmission, and modulation of pain stimuli develop the perception of the subjective emotional experience of pain. Many factors other than the stimulation of nociceptors influence the final perception of pain. The discrete cognitive processes and pathways involved in the interpretation and experience of painful stimuli remain a mystery and are affected by factors such as cultural expectations, personality, experiences, and the underlying emotional state. Many of these factors, and therefore the subsequent perception of pain, can be greatly influenced by both pharmacologic and nonpharmacologic interventions. For drugs such as nitrous oxide and low-dose opioids, much of their effect is on the cognitive interpretation and emotional reaction to pain rather than on the transmission of the pain stimulus. Noninvasive techniques (e.g., distraction and hypnosis) can limit pain perceptions and increase tolerance. Changes in a way a person experiences pain based on previous experiences and learned behaviors are referred to as cognitive sensitization.

**Reflex Responses to Pain**

There are two types of reflex responses to nociceptor input: spinal segmental (or suprasegmental) and cortical. Spinal reflexes are generated by the transmission of nociceptive impulses from the dorsal horn to motor and autonomic neurons in the spinal cord, provoking responses such as tachycardia, vasoconstriction, paralytic ileus, and muscle spasm. Suprasegmental reflexes are transmitted through ascending tracts to the brainstem, hypothalamus, and cortex, where withdrawal reflexes and autonomic responses occur in conjunction with conscious responses. The autonomic reflex responses to pain are variable and cannot be used to quantify pain in an individual. Reflex responses to nociceptive input are summarized in Box 186-2.

**Endorphin System**

The endorphin system is a neuroendocrine system that serves to modulate responses to pain and stress. It consists of widely scattered neurons that produce three types of opioids: beta-endorphin, the met- and leu-enkephalins, and the dynorphins. These opioids act as neurotransmitters and neuropeptides at three major classes of receptors—mu, delta, and kappa—and produce analgesia and counter the stress response. These receptors are described in Table 186-2.

Under normal circumstances, the endorphin system serves to decrease pain and stress after a person has adequately dealt with the inciting noxious stimuli. It normally is a responsive system that can have an increased or decreased effect in order to produce the appropriate response to a painful event. Like other neuroendocrine systems, it produces feedback inhibition of itself with increasing stimulation. During prolonged periods of pain with high levels of stimulation, the system can become
Acute versus Chronic Pain

Acute pain is usually associated with an identifiable pathologic condition and serves an adaptive function by warning the individual that an illness or injury exists, motivating the person to stop any activity that is causing the pain, look for a cause, seek help, and avoid the stimulus in the future.

Acute pain becomes chronic pain when the pain pattern persists, in changed or unchanged form, after the original physiologic insult has apparently resolved. All chronic pain starts as acute pain, but only a small subset of patients with acute pain go on to develop chronic pain (Table 186-3). The physiologic transition from acute to chronic pain is a complex process with both physiologic and psychosocial components. It is likely that the development of chronic pain is related to the treatment of acute pain.

Acute pain serves an important purpose in that it stimulates a person to protect the injured area and seek help, and the neurochemical factors that contribute to pain generally are a part of the recruitment of tissue repair mechanisms. As an injury heals, these adaptive responses may become maladaptive if the pain persists, leading to a decreased range of motion and decreased function of the area that could lead to increased susceptibility to injury and pain. Pain also causes a stress response, which is also initially adaptive in the face of injury. A prolonged stress response, however, causes an impaired immune system, hypercoagulable states, sleep disturbances, anxiety, and depression. Chronic pain is very common, and a large number of patients with chronic pain are seen in the ED.

It can be difficult to determine at what point an adaptive pain response becomes maladaptive or at what point acute pain becomes chronic. When a clear physiologic injury is related to the pain and its progression can be assessed, the determination is more straightforward. If an injury can be identified and can be expected to improve, the pain can be considered acute. Chronic pain is not related to tissue injury or is related to tissue injury that is not expected to resolve, is past the time by which it should have resolved, or is expected to progress.

MANAGEMENT PRINCIPLES

Pain Assessment

The early, accurate recognition and assessment of a patient’s pain are the most important aspects of effective acute pain management. When pain is inadequately treated, inaccurate assessment is very likely the root cause of the problem.

The degree to which a person experiences pain is a complex and subjective interaction between the physical stimulus and the patient’s cognitive and emotional state. It is clear, however, that the degree of pain a patient perceives is not directly determined by the degree of physiologic injury. Patients in the ED with the same injury may display completely different amounts of pain. Therefore, pain treatments, analgesic requirements, and the way a patient describes pain cannot be uniformly described based on the nature of a patient’s injury, and each patient must be individually and repeatedly assessed.

The assessment of pain depends on the patient’s ability to communicate the nature of the painful experience to the physician and on the physician’s ability to obtain this information. Unfortunately, there is no test or physiologic index to measure pain reliably. Objective observations, such as hypertension, diaphoresis, or tachycardia, do not correlate well with the degree of pain present. Pain assessment is made through an indirect estimation by the patient’s caregivers. Since pain cannot be objectively measured, a physician’s assessment depends on communication with the patient, both verbal and nonverbal. Barriers to communication between patients and physicians, including linguistic, socioeconomic, and cultural differences, limit the ability to assess pain. Because effective treatment is based on the assessment of pain, patients who have difficulty communicating are at particular risk of undertreatment of their pain (oligoanalgesia). Groups at risk include infants and children; patients whose cultural background differs significantly from the treating physician’s; and patients who are developmentally delayed, cognitively impaired, under severe emotional stress, or mentally ill. The accurate assessment of pain in the face of communication barriers is a difficult yet important challenge to overcome in treating pain adequately.

Oligoanalgesia

Oligoanalgesia, the inadequate treatment of pain, is detected in most studies of pain in the ED. Data from the National Hospital Ambulatory Medical Survey evaluated all isolated closed fractures of extremities and clavicle and showed that only 64% of patients received an analgesic and only 42% received an opioid. Children, the elderly, and patients from social and ethnic minorities exhibit oligoanalgesia the most frequently.

Even when analgesia is administered in the ED, there frequently is a long delay. When opioids are used, they frequently are given in subtherapeutic doses. One study of trauma centers shows that of the 38% of patients who received an analgesic, the average time of administration of the first dose of analgesic was 109 minutes after arrival.

For a wide variety of reasons patients do not receive adequate analgesia, and they are not all related to the assessment of pain. Many are due to misconceptions about the safety and efficacy of various treatments and about the effect of pain treatment on a patient’s evaluation.

Pain Measurement

The use of numeric rating scales, employing a verbal 0 to 10 “none to worst imaginable” score, are ubiquitous in the ED and other settings where acute pain is managed or inflicted. Visual analogue scales, usually consisting of a 10-cm straight line with anchors at either extreme (similar to verbal scales), are used in research in order to provide continuous data for analysis but offer little practical advantage over verbal reports for clinical use. Including a pain scale as a part of vital signs is now mandated by the Joint Commission (Fig. 186-4) and is a routine part of care. This encourages clinicians to initially and frequently communicate with patients to assess their pain and its response to interventions in order to improve the management of their pain.

Figure 186-4. Common pain rating scales.
Patient-derived pain scales are only useful if the patient can understand the question being asked. Using a numeric or verbal rating scale requires understanding the language it is being asked in or being able to read the anchors. It also requires an ability to assign a concrete value to the abstract concept of pain. In general, children younger than 7 years are unable to successfully accomplish this. The FACES pain scales are designed for children younger than 7 who are verbal and may be used to describe their pain. These scales have a series of cartoon faces expressing a range of emotions from happiness to severe distress. The child is asked to point to the face that corresponds to how he or she feels. These scales require less of an abstract reference than numeric and verbal scales and are useful in assessing toddlers and cognitively impaired adults.

In preverbal children, observer-derived scales may be used. These include scales such as the Modified Pre-Verbal, Early Verbal Pediatric Pain Scale (M-PEPPS), and the Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS) for preverbal children and the CRIES scale for neonates. These scales use a scoring system for observed criteria that is reproducible between observers, making them useful for research, but they have little clinical utility over the physician’s or parents’ overall impression of the child’s pain.

Although these scales are validated for use in the ED, a great deal of variability is described both within and between patients for a given stimulus. Numeric rating scales can be used as communication tools between the patient and the physician to talk about pain, but care must be taken against using the scores derived from the scale as an absolute indicator of pain. The score a patient uses to describe pain has as much to do with how much he or she wants action to be taken on that report as it does a description of the pain relative to previous experiences. A patient reporting 10/10 pain probably wants something to be done about it. If other concerns are more pressing, the patient may describe the pain from the same injury as 2/10. As a patient undergoes treatment, changes in the pain scores represent satisfaction from the treatment and a desire for further treatment, more than any change in the condition. Nevertheless, pain scores remain the most accurate measure of assessing a patient’s pain and pain treatment and should be used frequently during the assessment of patients with pain. Treatment should be targeted to a goal of reducing the pain score (e.g., by 50% or to below 3/10) rather than a particular (maximum) dose of the analgesic.

### Treatment

The basic approach to the treatment of pain can be broken into four main treatment groups: (1) acute pain, (2) chronic pain, (3) recurrent pain, and (4) chronic pain of malignancy. Therapy for groups 2–4 should involve a long-term multidisciplinary approach in order to treat the multiple manifestations of these diseases, where the plan from the emergency physician fits as part of an ongoing strategy.

Acute and chronic pains have different physiologic etiologies and thus require different treatment approaches (Fig. 186-5). The main difference in the treatment of acute versus chronic pain, in terms of the treatment of the actual perception of pain, is that it cannot be assumed that chronic pain will resolve, and treatments that are sustainable with side effects that can be controlled must be selected.

### Chronic Pain

The assessment of pain in the absence of acute or obvious physical injury requires a great deal of communication skill on the part of the physician and the patient. Many patients with chronic pain develop a great deal of experience, some of it adaptive and some maladaptive, in describing their pain and interacting with physicians in order to receive pain treatment. Many behaviors such as exaggerating symptoms or attempting to manipulate providers develop around the patient’s low expectations of receiving pain relief. These behaviors, combined with the negative psychosocial effects and sense of futility associated with chronic pain, can complicate the evaluation process and the care of chronic pain patients.

The assessment of chronic pain can represent some of the most challenging situations in which to obtain an accurate history. Patients who are having a difficult time describing their pain should be encouraged with detailed questions about the pain, combined with multiple examples, comparisons, and summarizing statements, in order to facilitate accurate communication. Assuring the patient that the questions are intended to aid understanding and to enable treatment of symptoms as effectively as possible can facilitate the development of a common goal and help establish the trust necessary to develop an effective treatment strategy.

Patients with chronic pain can present either with an exacerbation of their chronic pain in the setting of their ongoing
therapy or with untreated chronic pain due to a gap in or a lack of appropriate treatment. These two situations require different treatment approaches. For chronic pain patients with an exacerbation in their pain exceeding the pain control of their usual treatment strategy, treatment can be approached in a similar fashion to acute pain, with the goal of controlling the exacerbation and returning them to their baseline therapy. Many patients with chronic pain, however, are in comprehensive treatment programs, most of which involve a “contract” with respect to where they will seek their care (e.g., not in an ED) and their medications (always from the pain center). For such patients, review of the pain management plan in the medical records or contact with the physician on call for the pain center is desirable before embarking on a treatment strategy.

Patients with chronic pain who have a gap in their baseline treatment or have never established appropriate treatment for chronic pain (e.g., patients who have linked together the acute treatment plans of multiple providers but lack a consistent treatment approach) require an approach that takes into account the fact that a chronic pain treatment plan needs to be established.

Patients with no ongoing treatment plan who are identified as having chronic pain should have a basic chronic pain treatment plan implemented during their ED visit. Patients should be using acetaminophen if not contraindicated and an nonsteroidal anti-inflammatory drug (NSAID) if it can be tolerated. Tramadol may be helpful in certain cases, and adjuvants appropriate for neuropathic or central pain may be added if appropriate. Opioids should not be prescribed until these other treatments are maximized and should be added in addition to these other therapies rather than as an alternative. In general, opioids for chronic pain management are in the domain of the ambulatory pain center or primary care physician and should be avoided in the ED and by prescription on discharge.

**Recurrent Pain**

Recurrent pain is a subset of chronic pain and describes patients who have few symptoms in between repeated episodes of similar pain. It can include such disorders as back pain, myofascial pain syndrome, migraine syndrome, sickle cell disease, and inflammatory bowel disease. The approach to the treatment of recurrent pain in the ED is similar to that of acute pain, except that prevention must be considered and strategies that can be safely repeated should be employed. Therapies that may suppress future episodes, such as physical therapy for back pain, should be planned to start in between exacerbations.

**Chronic Pain of Malignancy**

Chronic pain due to malignancy is approached differently from other causes of chronic pain. Chronic malignant pain is similar to acute pain in its relation to ongoing nociceptive stimulation and similar to chronic pain in its duration and psychosocial effects. The medications used, for the most part, are similar to those used for acute pain. Similarly to chronic pain, the psychosocial effects of the pain must also be addressed as part of an effective treatment strategy. Patients with a significant change in the pattern of their chronic pain caused by cancer or a terminal illness, as with other chronic pain patients, should be evaluated for a new process to account for the pain. Opioids, especially in long-acting or transdermal preparations, should be used liberally to bring pain relief in patients with terminal illnesses.

**Neuropathic Pain**

Usually, activation of the sympathetic system does not result in pain. In the setting of nerve injury, however, it appears to modulate the development of hyperalgesia and allodynia and is associated with a wide variety of neuropathies. Complex regional pain syndrome (CRPS) is a term that includes most sympathetically maintained pain. CRPS type 1 (sometimes referred to as reflex sympathetic dystrophy) develops after an injury and is usually in the distribution of a peripheral nerve. It is associated with hyperalgesia, allodynia, changes in skin blood flow, and sympathetic dysfunction. CRPS type 2 (sometimes referred to as causalgia) is associated with burning pain and allodynia in the distribution of an injured nerve and is not usually associated with sympathetic symptoms. Some evidence indicates that CRPS can be prevented with opioids prior to the occurrence of an injury83,85 and that opioids are ineffective after the injury.84 Clonidine, N-methyl-D-aspartate receptor antagonists, and γ-aminobutyric acid (GABA) receptor agonists are more effective than opioids for these conditions.83

Antidepressants have effects on neuropathic pain that do not depend on their mood effects. A meta-analysis of 39 placebo-controlled trials using first-generation tricyclic antidepressants found benefits in a variety of chronic pain syndromes.87,88 They are generally used as analgesics for central and neuropathic pain but can be useful as antidepressants in most chronic pain conditions. For chronic pain that is not thought to be central or neuropathic, other antidepressants, such as serotonin reuptake inhibitors, may be safer and more effective.

Several anticonvulsants, including gabapentin, phenytoin, carbamazepine, and valproic acid are described for neuropathic pain with lancinating or burning properties. Carbamazepine is used most frequently for trigeminal neuralgia, postherpetic neuralgia, and diabetic neuropathy. Gabapentin is described for both types of CRPS, postherpetic neuralgia, and diabetic neuropathy.

**Acute Pain**

Acute pain follows injury and usually disappears as the injury heals. When the cause is uncertain, establishing a diagnosis is a priority, but symptomatic treatment of pain should be initiated promptly, titrated to an acceptable level of relief, and continued while the investigation is proceeding. It is rarely appropriate to delay analgesic use until a diagnosis is made. There is no evidence that the administration of adequate doses of opioid analgesia to establish patient comfort impairs the physician’s ability to diagnose the cause of the painful condition. To the contrary, administration of analgesia may enhance the accuracy of physical examination. For example, when the woman with severe pelvic pain receives adequate analgesia before pelvic examination, she is more likely to be able to assist the physician in localizing the pain to one side or the other.92,93

**Analgesic Agents**

**Opioid Analgesic Agents**

In 1680, Sydenham wrote “Among the remedies it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.”94 Centuries later, this statement is still accurate, and titrated opioids are the mainstay of therapy for acute pain. The beneficial effects of opioids have been well documented for centuries, as have their toxic-
ity and potential for abuse. Opioids, however, are often poorly used in clinical practice. Concerns about inducing opioid toxicity or dependence and a poor understanding of the pharmacokinetics of the drugs lead to inadequate dosing and excessively infrequent dosing intervals. The safety of the short-term use of opioids for acute pain, however, in terms of both toxicity and their likelihood of causing future dependence, is shown in a wide variety of studies. Opioids should be the first-line agents in the management of acute severe pain. Table 186-4 lists commonly used opioid agents.

**Mechanism of Action and Toxic Effects.** Opioids bind to specific endorphin system receptors located throughout the nervous system that suppress pain detection peripherally, modify pain transmission in the spinal cord and thalamus, and alter the perception of pain at the level of the cortex. A variety of endorphin receptors are currently defined (see Table 186-2), and the unique actions of various opioids are determined by the specific binding properties of the agent to the various receptors.

Opioids also suppress the medullary cough center (antitussive) and decrease the medullary sensitivity to carbon dioxide (respiratory depression). They can activate the chemoreceptor trigger zone, causing nausea or vomiting, but this is relatively infrequent. They decrease bowel motility and smooth muscle function, causing constipation and, rarely, urinary retention. To a varying degree, some opioids destabilize mast cells in a dose-dependent fashion, causing histamine release, with urticaria, pruritus, and, sometimes, orthostatic hypotension. Any

*IV, intravenous; NA, not applicable; PR, per rectum.*
of these side effects can significantly limit therapy, especially in the acute setting. The occurrence of these side effects varies among individual patients and opioids, but tolerance of many of them develops shortly after the initiation of therapy. Most patients tolerate opioids very well, and prompt relief of severe pain often reduces nausea and vomiting.

The most common side effect of opioids is constipation, related to opioid binding to receptors located in the antrum of the stomach and proximal small bowel.195 Tolerance to this does not develop with prolonged use. Some opioids may cause less constipation than others, and parenteral and transdermal administration routes may be superior to oral (PO) due to decreased exposure of the gut to the opioids.96,97 Constipation can be anticipated with long-term (more than a few days) opioid use, and an active laxative, such as senna, lactulose, or bisacodyl, should be prescribed as needed.

Nausea and vomiting can occur with the administration of opioids, especially in opioid naïve patients, but routine coadministration of an antinauseant with the opioid, once an almost universal practice, is not indicated. It is impossible to distinguish whether the nausea and vomiting are caused by the opioid or the acute pain for which it is administered. Nausea and vomiting in the context of persistent acute pain after opioid administration require additional opioid and an antinauseant, such as promethazine, prochlorperazine, or one of the 5-HT3 receptor antagonists (e.g., ondansetron).

True immunoglobulin-mediated allergies are rare for morphine and other opioids, but many patients experience mild pruritus of the trunk and face after parenteral administration. This is related to histamine release from opioid receptors on mast cells and does not constitute an allergy to opioids. Often, it appears as localized urticaria that tracks up the vein after intravenous (IV) administration of an opioid, especially morphine. Rarely, bronchospasm may be seen in patients with reactive airway disease. The effect usually subsides rapidly, and no treatment is required.

Sedation and respiratory depression can occur with opioid administration for acute pain but are usually mild and self-limited. The underlying mechanism of respiratory depression is central stimulation of the μ receptor. The combination of opioids with other sedating agents, such as benzodiazepines, can increase the likelihood of respiratory depression. Patients with underlying hepatic or renal dysfunction may be at increased risk because of inability to clear the drug normally. Respiratory depression rarely occurs in the context of acute severe pain, and fear of respiratory depression should not deter the clinician from adequately relieving the pain. Pain is a powerful physiologic stimulant of respiratory drive, however, and if the source of the pain is removed, such as by local anesthesia or the reduction and stabilization of a fracture, patients who had previously tolerated a dose of an opioid may develop respiratory depression.99 Transient respiratory depression usually responds to simple verbal or tactile stimulation and rarely requires reversal.

Tolerance and physical dependence are common with prolonged use of opioids. Physical dependence is defined by the occurrence of opioid withdrawal syndrome following abrupt cessation, rapid dose reduction, or administration of an antagonist. Tolerance is a phenomenon that occurs after prolonged exposure to opioids and is characterized by the diminution of an opioid’s effect over time. Normal expected results of the prolonged use of opioids should be accounted for in planning the use of opioids for extended periods and do not represent addiction. Addiction is a potential risk associated with prolonged opioid use, which often limits the use of opioids.100 The term addiction refers to a neurobiologic disease, with many factors influencing its development and manifestations. It is characterized by compulsive drug use, continued use despite harm, and craving. The iatrogenic creation of opioid addiction, a new addiction where one did not previously exist, is a relatively rare phenomenon.101 The results of the Boston Drug Collaborative Study show that only 4 in 11,892 inpatients treated with opioid analgesic agents developed new opioid abuse.102

**Pseudoaddiction** describes patient behaviors that may occur when pain is undertreated.103 Patients with unrelieved pain may become focused on obtaining medications and otherwise seem inappropriately “drug-seeking.” Behaviors such as illicit drug use and deception can occur in the patient’s efforts to obtain relief. Pseudoaddiction can be distinguished from true addiction in that it resolves when pain is effectively treated.

**Suggestion of Drug-Seeking Behavior.** Some patients feign or exaggerate pain in order to receive opioids.104 A physician’s perception that a patient is drug-seeking is associated with decreased treatment of the patient’s pain and is associated with a patient’s ethnic background, making this perception a possible source for bias in the treatment of pain.105 Care must be taken both to identify such behavior when it exists and to do so accurately. Patients with repetitive episodes may benefit from a multidisciplinary review to establish specific recommendations for their care when they present to anyone other than their primary pain management provider.

**Administration**

The goal of the administration of opioids is to attain effective analgesia with minimal adverse effects and then to maintain it. The effects of opioids vary among individuals. There is no “ceiling effect” to their potency, neither is there a standard, fixed, or weight-related dose that can produce a given clinical effect. The correct dose a particular patient requires at a particular time can only be determined by repeated assessment of the degree of pain relief and any adverse effects the patient may be manifesting. The use of opioids therefore requires titration based on frequent and accurate assessments of the effects of any dose given.106 The most effective and safest way to achieve pain relief is to use a deliberate IV titration.

The intramuscular (IM) route of administration of opioids has several disadvantages and is not advised for treatment of acute pain (Box 186-3). The principal limitation is that it does not allow effective titration. The time to achieve significant pain relief from an IM injection varies from 20 to 60 minutes, offering no advantage over the PO route. If the dose is inade-
PART V  ■  Special Populations

/ Section Essay  ▶  The Patient in Pain

Opioids can be delivered through the PO transmucosal or intranasal mucosal route. The opioid buprenorphine can be given by sublingual route. Fentanyl is available in an impregnated, sweetened matrix called a Fentanyl Oralet (PO transmucosal fentanyl citrate). Nasal fentanyl, butorphanol, and sufentanil also produce rapid clinical effects.

The optimal use of IV opioids requires administering an initial “loading” dose, assessing its analgesic effect, and then administering frequent (every 10–15 minutes) repeated doses until analgesia is achieved, followed by doses at regular intervals to prevent the return of significant discomfort. The best way to determine the need to administer another dose of opioid is to use the patient’s subjective impression. Patient-controlled analgesia uses a computerized delivery system that allows patients to self-administer a prescribed dose of opioid based on their own determination of need. Patient-controlled analgesia has been demonstrated to be safe and effective for sickle cell pain crisis in a pediatric ED.

Specific Agents

Morphine. Intravenous morphine is often the first choice for treatment of acute severe pain in ED patients and is the opioid analgesic agent with which all other opioids are compared. When administered IV, morphine reaches its peak of action in 15 to 20 minutes and has a half-life of 1.5 to 2 hours in healthy young adults and slightly longer in the elderly. Its duration of action is 3 to 4 hours. An appropriate loading dose for acute severe pain is 0.1 to 0.15 mg/kg IV, augmented by repeated doses of 0.05 mg/kg every 15 minutes until pain is relieved. Oral administration of morphine can be an effective option for moderate or severe outpatient pain, but only 20% of the ingested dose reaches the tissues after first-pass metabolism. There is no validity to the perception that morphine causes more smooth muscle spasm than other opioids and should be avoided in patients with biliary or renal colic.

Morphine is hydrophilic in nature, which delays its transport across the blood-brain barrier relative to more lipophilic opioids and delays its onset of action. This results in it having a longer duration of action (4–5 hours) than its half-life (2–3 hours). Morphine is primarily metabolized by conjugation into a 3-conjugate and 6-conjugate form in the liver. The 3-conjugate form (normorphine) has no opioid analgesic activity and rarely accumulates. T3G is only 30 to 60 minutes. It is metabolized by the P450 system and produces analgesia within 1 to 2 minutes after IV administration. Morphine releases less histamine than morphine, is associated with fewer peripheral effects at an equianalgesic dose, and thus is an excellent choice for treating pain in patients with bronchospastic lung disease. It is more frequently associated with respiratory depression with regular use than morphine, and patients receiving infusions of the drug should be monitored with direct observation, supplemented by pulse oximetry or capnography. ED use of fentanyl is associated with a very low (1.1%) incidence of potentially serious complications.

Fentanyl. Fentanyl is a synthetic opioid that is highly lipophilic and produces analgesia within 1 to 2 minutes after IV infusion. It also redistributes rapidly, and its duration of action is only 30 to 60 minutes. It is metabolized by the P450 system into inactive metabolites. Drug accumulation and toxicity may occur after tissue saturation following a prolonged infusion, but this is unlikely to happen during acute therapy. Fentanyl’s short duration of action makes it highly titratable and ideal for use in patients who require serial examinations, such as trauma patients with possible occult head injury.

Fentanyl releases less histamine than morphine, is associated with fewer peripheral effects at an equianalgesic dose, and thus is an excellent choice for treating pain in patients with bronchospastic lung disease. It is more frequently associated with respiratory depression with regular use than morphine, and patients receiving infusions of the drug should be monitored with direct observation, supplemented by pulse oximetry or capnography. ED use of fentanyl is associated with a very low (1.1%) incidence of potentially serious complications. High or repeated doses of fentanyl may produce muscle rigidity. This side effect usually occurs with anesthetic doses greater than 15 μg/kg and may be so severe that it interferes with respiration but is exceedingly rare at doses used for analgesia. This rigidity does not uniformly respond to naloxone but is abolished by neuromuscular blockade. Fentanyl can be administered IV, transmucosally, or transdermally. Perhaps the greatest disadvantage of meperidine is that it is metabolized by the cytochrome P450 system to the active metabolite normeperidine, which is produced in much larger quantities than the toxic metabolite of morphine at therapeutically equivalent doses, and causes CNS toxicity. Normeperidine has a half-life of 12 to 16 hours and blocks muscarinic receptors, resulting in significant anticholinergic effects and subsequently causing agitation and delirium. This eventually leads to seizures, hallucinations, and psychosis as the drug accumulates. Normeperidine is renally excreted and has a longer half-life in patients with decreased renal function. Repeated doses of meperidine should be avoided.

Of particular concern is the potentially lethal interaction of meperidine with monoamine oxidase inhibitors. Meperidine can also cause a serotonin syndrome in patients who are taking a selective serotonin reuptake inhibitor or other serotonin agonist. Meperidine is no longer a formulary drug at many hospitals.

Hydromorphone. Hydromorphone is a semisynthetic derivative of morphine that is a potent analgesic agent, increasingly used in the management of acute pain in the ED. This P450 metabolite of hydrocodone is seven times more potent than morphine when given parenterally and has a similar duration of action to morphine. Although 7 mg of morphine is equivalent to 1 mg of hydromorphone, nurses are more likely to administer the “low” milligram doses of hydromorphone to patients with acute pain than the “higher” equipotent doses of morphine. Pruritis, nausea, and vomiting may occur less frequently than with morphine at equianalgesic doses. It is conjugated primarily into hydromorphone-3-glucuronide (H3G) in the liver and is excreted renally. H3G is for the most part inactive, so hydromorphone is better tolerated than morphine in elderly patients and those with hepatic impairment. Patients with renal insufficiency may be at some risk of neurotoxicity after prolonged exposure due to H3G accumulation. True allergy to opioids is rare, but patients allergic to morphine do not always have cross-reactivity with hydromorphone. Hydromorphone can be given IV or PO. A rectal (PR) preparation is available in the form of 3-mg PR suppositories.

Meperidine. Meperidine (Demerol), although once widely used, has several disadvantages compared with morphine and other parenteral opioids and has no role in the ED management of acute pain. The duration of action of meperidine is only 2 to 3 hours, which is less than that of morphine. Perhaps the greatest disadvantage of meperidine is that it is metabolized by the cytochrome P450 system to the active metabolite normeperidine, which is produced in much larger quantities than the toxic metabolite of morphine at therapeutically equivalent doses, and causes CNS toxicity. Normeperidine has a half-life of 12 to 16 hours and blocks muscarinic receptors, resulting in significant anticholinergic effects and subsequently causing agitation and delirium. This eventually leads to seizures, hallucinations, and psychosis as the drug accumulates. Normeperidine is renally excreted and has a longer half-life in patients with decreased renal function. Repeated doses of meperidine should be avoided.
Nebulized fentanyl is described for the treatment of acute pain in patients without IV access at doses of 3 µg/kg, as has intranasal administration.\textsuperscript{116,117}

**Oxycodone.** Oxycodone is a strong opioid agonist that is highly bioavailable in PO form. It is widely available in combination with acetaminophen or aspirin as well as by itself. It is also available in long-acting PO formulations. Its bioavailability is described to be between 0.60 and 0.85, which is higher than other opioids. It is quickly and efficiently absorbed, with abuse potential. Oxycodone is not available in a parenteral form in the United States, although studies have found its IV form to be equianalgesic to morphine. Similar to the other opioids, oxycodone’s analgesic effects are dose-dependent. A 15-mg dose has a similar efficacy to 10 mg of IV morphine. The onset of action of PO oxycodone is 20 to 30 minutes.\textsuperscript{118}

Oxycodone is a prodrug that undergoes hepatic metabolism into oxymorphone, a strong opioid agonist that principally accounts for its analgesic effects, and the inactive metabolite noroxycodone. Similarly to codeine, 10% of patients do not metabolize oxycodone well and do not generate the functional metabolite, which means that they require very large doses of oxycodone to achieve analgesia. This effect can also be caused by agents that compete with oxycodone for CYP2D6 metabolism, such as neuroleptics, tricyclic antidepressants, and selective serotonin reuptake inhibitors. Cases of serotonin syndrome are reported when serotonin reuptake inhibitors and oxycodone are given together.\textsuperscript{119,120}

**Hydrocodone.** Hydrocodone is metabolized in the liver to hydromorphone. It provides greater pain relief when combined with acetaminophen or NSAIDs than either component does alone. In two small studies, hydrocodone-acetaminophen (5 mg/500 mg) provides similar analgesia to codeine-acetaminophen (30 mg/500 mg) in patients with acute musculoskeletal pain or those who had undergone dental surgery.\textsuperscript{121,122} Hydrocodone may cause more drowsiness and dizziness but less nausea than codeine. It is less effective than oxycodone-acetaminophen combinations.\textsuperscript{123} Hydrocodone is usually administered alone, 5 to 20 mg PO every 4 to 6 hours. Hydrocodone-acetaminophen combination tablets are commonly prescribed as one to two tablets every 4 hours as needed for pain.

**Codeine.** Codeine is a commonly prescribed opioid, usually in combination with acetaminophen. Codeine is a weak opioid receptor agonist and has little role in the abluminal treatment of pain, unless oxycodone is not available. Codeine is thought to exert its effects through metabolism into morphine and other metabolites in the liver.

Approximately 10% of the population metabolizes codeine poorly and experiences nausea, constipation, and pruritus without pain relief. Although often prescribed for mild to moderate pain, codeine is a poor choice because of its tendency to cause side effects, especially nausea, cramping, and constipation, at doses that provide limited analgesia.

**Propoxyphene.** Propoxyphene has limited indications for use. Many studies show its analgesic efficacy to be no better or only marginally better than placebo.\textsuperscript{124} Its metabolite, norpropoxyphene, can accumulate with repeated or large doses and can cause refractory seizures, respiratory arrest, and significant risk of death from torsades de pointes.\textsuperscript{125} There is little evidence to support its use alone or combined with acetaminophen for acute pain, and it generally should not be used in the ED or prescribed for outpatient management of pain.\textsuperscript{126}

**Methadone.** Methadone has several unique features that distinguish it from other opioids. It has no known neurotoxic or active metabolites, has high bioavailability, and, in addition to being a strong opioid agonist, has N-methyl-D-aspartate antagonist and serotonin reuptake–blocking properties. It has a slow elimination half-life of 27 hours due to its lipophilicity and tissue distribution. This slow clearance of methadone is the basis for its use in maintenance therapy, because it can delay the onset of opioid withdrawal symptoms for up to 24 hours. The duration of its analgesic effects, however, is closer to 6 to 8 hours. The discrepancy between the duration of action of analgesia and the duration of the prevention of withdrawal symptoms is due to the biphasic elimination of the drug and its redistribution.\textsuperscript{127}

**Naloxone.** Naloxone is an opioid antagonist that can be given IV, IM, SC, or via an endotracheal tube. It reverses the effects of opioids and is usually used in the setting of severe adverse events or recreational opioid overdose. It can precipitate physiologic withdrawal in patients who are opioid-dependent. Its duration of action is 45 minutes, which is shorter than that of most opioids, so care must be taken to monitor for the recurrence of the adverse event for which it was given after this time period. It is usually given in repeated titrated doses of 0.2 mg IV, until the adverse effect of the opioid is reversed. Careful titration allows for the smallest dose possible to be given so that as much of the analgesic effect of the opioid can be maintained as possible.

**Tramadol.** Tramadol is a synthetic oral compound that is a weak mu agonist with some serotonin and norepinephrine reuptake qualities. Its analytic properties are thought to be primarily due to mu receptor agonism. Tramadol-induced analgesia, however, is only partially reversible by naloxone, suggesting its other properties play a role. Tramadol, as a selective mu agonist, should not cause physiologic dependence. Since its release, however, it has been associated with abuse and withdrawal similar to that of other opioids, but at a low enough rate that it remains an unscheduled drug. It is metabolized in the liver by the cytochrome P\textsubscript{450} system. One of its metabolites, M1, has an even greater mu-receptor affinity than tramadol and has an elimination half-life of 9 hours. Tramadol appears to have effects on GABA, norepinephrine, and serotonin receptors and the reuptake of the neurotransmitters, which may serve to activate descending pain modulation pathways.

Compared with traditional opioids, tramadol has a more favorable side effect profile and may present a lower risk of addiction with chronic use. The most common side effects, nausea, vomiting, dizziness, orthostatic hypotension, and sedation, are seen in as many as 17% of patients using it for chronic pain, with slightly lower rates occurring in patients receiving controlled-release versions.\textsuperscript{128} The occurrence of these side effects increases dramatically with increasing doses. Reports of overdose and fatalities have led to the addition of past or present histories of addiction to opioids as a contraindication for the drug. The use of tramadol with other serotoninergic medications (selective serotonin receptor inhibitors, monoamine oxidase inhibitors, and serotonin norepinephrine reuptake inhibitors) is associated with serotonin syndrome.\textsuperscript{129}

Tramadol is an efficacious pain medication at low doses. At increasing doses, it is associated with nausea and vomiting, limiting its use to low doses and effectively giving a ceiling to its therapeutic effect. Tramadol 37.5 mg combined with acetaminophen 325 mg has similar efficacy to hydrocodone 5 mg combined with acetaminophen 325 mg.\textsuperscript{130}

**Opoid Agonist-Antagonist Analgesic Agents**

The agonist-antagonist group of opioids was synthesized in an attempt to provide analgesia with little or no respiratory depression and abuse. It is believed that the analgesia provided by these agents is caused by agonist action at the kappa receptors, whereas the ceiling on respiratory depression is
caused by antagonism of the mu receptors. They have rates of abuse similar to those for standard opioids and a ceiling effect to their analgesia that limits their use to situations in which brief, limited analgesia is needed and respiratory depression is the principal adverse effect of concern—such as in the perinatal period. Nalbuphine can be used in these situations. Its major advantage is decreased respiratory depression. The half-life is 3.5 hours, and the effects of renal or hepatic disease on metabolism are not completely known. The usual therapeutic parenteral dose is 10 mg, but as with all other opioids, the dose must be individualized.

Opioid Use in Abdominal Pain

Historically, it was recommended that pain treatment be withheld from patients with abdominal pain in order to avoid confounding the diagnosis. These recommendations date from the turn of the 20th century, predating modern diagnostic techniques, and have no place in modern emergency care. Multiple studies confirm the safety of providing effective opioid analgesia to patients with undiagnosed abdominal pain, and no study has demonstrated any adverse effects.131-139

Nonopioid Analgesic Agents

Acetaminophen. Acetaminophen is the first-line agent for the treatment of both acute and chronic pain. It is the safest pharmacologic option for pain in children and adults. It has a high toxic-to-therapeutic ratio and lacks significant drug interactions compared with other pain medications.

Although acetaminophen has been in use since the 1880s, its pharmacologic mechanism of action is unknown. It has known analgesic and antipyretic activity, with no known peripheral anti-inflammatory effects. Its activity may be due to the inhibition of prostaglandin endoperoxide H2 synthase and a cyclooxygenase isoenzyme centrally.140 It may also affect the activation of beta-endorphin centrally.141 The analgesic actions of acetaminophen are comparable in magnitude to those of NSAIDs,142 and the analgesic effects of the combination of acetaminophen with an NSAID are additive.

Acetaminophen is metabolized in the liver primarily through conjugation to sulfate or glucuronides. A minor pathway for metabolism are not completely known. The usual therapeutic dose is 10 mg, but as with all other opioids, the dose must be individualized.

Nonsteroidal Anti-inflammatory Agents

NSAIDs inhibit cyclooxygenase (COX) and, as a result, the synthesis of prostaglandin, a key mediator of inflammation. The analgesic effect of NSAIDs is peripherally mediated by decreasing prostaglandin and effectively raising the threshold of activation of nociceptors. NSAIDs have synergistic effects with opioids and can reduce the amount of opioids needed to achieve pain relief in a patient.

Two COX isoenzymes mediate prostaglandin synthesis. COX-1 is present in all cells and plays an important role in homeostatic functions. COX-2 is induced by injury or inflammation and generates prostaglandins as part of the inflammatory process. Nonselective NSAIDs inhibit both COX-1 and COX-2, which results in multiple beneficial effects (reduction of inflammation, pain, and fever) but also some important undesirable effects.

As a group, and because of their wide use, NSAIDs are responsible for more serious drug-related side effects than any other class of analgesic drugs.128 The major side effects of NSAID analgesic agents are gastrointestinal (GI) bleeding, renal failure, anaphylaxis, and platelet dysfunction. The majority of these side effects occur in patients who are taking NSAIDs for chronic conditions. It is estimated that more than 100,000 hospital admissions and approximately 16,500 deaths each year from GI bleeding are related to NSAID use for osteoarthritis and rheumatoid arthritis.149 One survey estimated that for every 100,000 people taking NSAIDs each year, there are 300 GI-related deaths, 5 liver-related deaths, 4 renal-related deaths, and some congestive heart failure–related deaths.150

Limited evidence suggests that prostaglandins promote bone formation and that NSAIDs might inhibit the process, but this has not been established through properly conducted studies.150,151 There is no evidence that short term use of NSAIDs for analgesia after fracture is deleterious to healing.

In addition to prostaglandin, cyclooxygenase helps generate prostacyclin, a vasodilator that increases GI mucosal perfusion. In the stomach, COX-1 increases bicarbonate and mucin production, important for protecting the mucosal lining. Inhibition of COX-1 compromises these protections, predisposing patients to ulcers and bleeding, which are then exacerbated by concomitant NSAID-induced platelet dysfunction.152

COX-1 and COX-2 affect the cardiovascular system through the production of endothelial prostacyclin (vasodilatory) and thromboxane (platelet aggregation). Inhibition of COX-1 produces antiplatelet activity that may be cardioprotective by inhibiting thromboxane production more than prostacyclin. Inhibition of COX-2 inhibits prostacyclin production more than thromboxane and may produce prothrombotic effects, increasing the risk of cardiovascular events. In the case of nonselective COX inhibitors, these two effects appear to balance each other out, resulting in few changes in cardiovas-
cricular risk in studies of these drugs. In the case of selective COX-2 inhibitors, this may result in an increase in cardiovascular risk. 153-155

Prostaglandin produced by COX-1 causes renal vasodilation that maintains renal blood flow and the glomerular filtration rate (GFR). Inhibition of COX-1, especially in volumedepleted patients, can result in decreased GFR and even acute renal insufficiency. Sodium and water retention, hypertension, hyperkalemia, and acute renal failure may also ensue, especially in patients with congestive heart failure.

The most common adverse effect of NSAIDs is GI mucosal injury. In patients taking NSAIDs continuously for 1 year, 10 to 60% will develop abdominal pain, dyspepsia, or nausea and 2 to 4% will develop symptomatic ulcers. 156 Risk factors include age, concomitant use of warfarin or corticosteroids, congestive heart failure, diabetes, and coronary artery disease. There is evidence that cytoprotective agents such as misoprostol and proton pump inhibitors reduce this risk. 157 The relative risk for causing GI effects of the various NSAIDs are listed in Table 186-5.

**Drug Interactions**

**Aspirin.** NSAIDs may impair the cardioprotective effect of aspirin, although the available evidence is unclear and the use of daily aspirin for cardiac prophylaxis should not deter the prescribing of an NSAID for acute pain or inflammation. 158,159

**Oral Anticoagulants.** The antiplatelet effects of NSAIDs add to the anticoagulant properties of warfarin, compounding the risk of significant bleeding complications, especially from GI ulcers. Furthermore, NSAIDs displace protein-bound warfarin and cause subsequent increases in prothrombin times at a constant warfarin dose. 160 NSAID use is generally avoided in patients who are taking warfarin.

**ACE Inhibitors.** Concurrent use of NSAIDs with angiotensin-converting enzyme (ACE) inhibitors may impair renal function and impair the antihypertensive effects of ACE inhibitors.

**Diuretics.** Patients who are taking diuretics have a greater risk of developing renal failure because of NSAID-mediated decreased renal blood flow. Also, the natriuretic response to diuretics depends in part on prostaglandin-mediated vasodilatation.

**Risk Reduction When Added to Ibuprofen** 164

| Proton pump inhibitor | 0.09 |
| Misoprostol          | 0.57 |

GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

**Glucocorticoids.** Patients on corticosteroids have an increased risk of peptic ulcer disease. NSAIDs should generally be avoided in patients concurrently taking glucocorticoids unless closely supervised by an ambulatory care physician.

**Lithium.** NSAIDs enhance lithium reabsorption and may directly reduce lithium excretion, leading to increased lithium levels. CNS symptoms (drowsiness, confusion, vertigo, convulsions, or tremors), cardiac dysrhythmias, and QRS widening are warnings of lithium toxicity. The lithium dosage should be reduced when an NSAID is prescribed.

**Methotrexate.** Chronic coadministration of NSAIDs and methotrexate have resulted in prolonged, elevated blood levels of methotrexate, resulting in severe toxicity. A possible mechanism may be the decreased renal perfusion caused by NSAIDS, decreasing the elimination of methotrexate.

**Nonselective Cyclooxygenase Inhibitors**

NSAIDs combine analgesia and anti-inflammatory effects with low abuse potential and much different side effects from those for the opioids. Oral NSAIDs can be as effective as PO opioids for mild to moderate pain. Parenteral NSAIDs are available in many countries (only ketorolac is available in the United States) but offer little advantage over their PO forms. 157 Different patients respond differently to both the effects and the side effects of different NSAIDs; some experimentation may be necessary to determine the best choice for a particular patient. No particular NSAID is proven superior for any indication. Drug selection should depend on availability, side effect profile, convenience, and cost. Patients at risk for adverse events using NSAIDs are listed in Box 186-4.

**Ketorolac Tromethamine.** Ketorolac is the first nonopioid analgesic agent available for parenteral use in the United States, but it is rarely indicated because 60 mg of ketorolac administered IM is not superior to 800 mg of PO ibuprofen, which is easier to administer at a fraction of the cost. 161-162 Ketorolac’s main use is in the early treatment of renal colic (accompanied by a loading dose of IV morphine), a pain mechanism for which NSAIDs are particularly effective. If the patient can tolerate PO medication, 800 mg of PO ibuprofen is given instead.

**Ibuprofen.** Ibuprofen is the most widely used drug in the NSAID class. It is available over the counter in a variety of preparations, including tablets, liquid suspension, and sup-

**Box 186-4 Patients at Risk for Adverse Events Using NSAIDs**

1. Patients who are dehydrated or hypovolemic or who have impaired renal function are at increased risk for decreasing renal function or renal failure.
2. Patients with liver disease or congestive heart failure, in particular, those already taking ACE-inhibitors, ARBs, or diuretics, in whom liver or heart conditions may worsen.
3. Elder patients, particularly those at risk for GI and renal events.
4. Patients with asthma and known aspirin hypersensitivity are at an increased risk of bronchospasm.
5. Women in the third trimester of pregnancy. NSAIDs may prolong gestation or prematurely close the ductus arteriosus.
6. Patients who use tobacco or ethanol or who have a history of gastritis or peptic ulcer disease are at risk for peptic ulcer and GI bleed.

ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.
posterior. Ibuprofen is rapidly absorbed in the upper GI tract and has minimal interaction with other medications. The adult analgesic dose is 400 mg, and the anti-inflammatory dose is 600 to 800 mg. No NSAID has been shown to be more effective as an analgesic than ibuprofen 400 mg, including ibuprofen 800 mg.161,164,165

COX-2-Specific Inhibitors

The discovery of two distinct cyclooxygenase isoenzymes (COX-1 and COX-2), one (COX-2) associated mostly with pain and inflammation, raised hope that an effective new class of analgesics could be developed. These would control pain and inflammation with fewer adverse effects (particularly GI mucosal injury) than traditional NSAIDs. Despite great initial promise, a dramatic pricing differential, and intensive marketing, the two classes of NSAIDs (nonselective COX inhibitors and selective COX-2 inhibitors) perform similarly in clinical use, with similar side effect profiles. Agents that selectively inhibit COX-2 are expected to cause less ulceration and have a lower risk of bleeding. COX-2 has been identified in normal gastric mucosa, however, and selective inhibitors may not confer any GI-protective advantage. COX-2 inhibitors may have prothrombotic effects from greater inhibition of prostacyclin than thromboxane, thus increasing the risk of cardiovascular events. COX-2 inhibitors also decrease renal perfusion, thereby decreasing renal function and reducing sodium excretion by the same amount (approximately 20%) as NSAIDs.

No studies on COX-2 inhibitors’ effectiveness in pain relief have been conducted in ED settings. COX-2 inhibitors are superior to placebo and equivalent to COX-1 inhibitors in treating acute postoperative dental pain, postoperative orthopedic pain, primary dysmenorrhea, and osteoarthritis. There are no studies comparing COX-2 inhibitors’ efficacy in renal colic, biliary colic, acute gout, headache syndromes, sickle cell crisis, or acute musculoskeletal or soft tissue injury. COX-2 inhibitors should not be combined with NSAIDs because of their similar pharmacologic effects. COX-2 inhibitors have similar interactions as NSAIDs with ACE inhibitors, antihypertensive agents, anticoagulants, and lithium.

Given their price, potential for adverse cardiovascular events related to long-term use, and lack of superior safety or efficacy compared with nonselective NSAIDs, there is little or no role for COX-2 inhibitors in the ED or as a discharge prescription.

Skeletal Muscle Relaxants

Skeletal muscle relaxants are advocated as an adjunct to analgesics in the management of musculoskeletal pain with a “spasm” component, principally back pain. Despite the common use of skeletal muscle relaxants, relatively little data exist on their role in the treatment of pain. Studies show that muscle relaxants, such as cyclobenzaprine, are indistinguishable from ibuprofen in analgesic effect but have an increased side effect profile. Although a Cochrane Systematic Review claims that skeletal muscle relaxants are more effective than placebo with respect to relieving acute low back pain, it is not possible to discern any differential or additive effect to that of NSAIDs when the primary trials are reviewed.166 These drugs have not been found to be of benefit in the treatment of chronic low back pain, which is their most common use.167

Skeletal muscle relaxants should not be used in the management of acute musculoskeletal pain as a substitute for proper doses of effective analgesics unless there is a high degree of anxiety accompanying the pain, and an anxiolytic is felt to be helpful. In that case, a benzodiazepine, such as diazepam, 5 mg three times daily, may be an effective adjunct for pain control. Based on (a lack of) outcome benefit, there is no indication for the prescription or use of the other muscle relaxants shown in Table 186-6.

Benzodiazepines have hypnotic, anxiolytic, antiepileptic, and antispasmodic properties. Muscle relaxation is probably due to GABA-mediated presynaptic inhibition at the spinal cord level but has not been shown to be clinically relevant. Diazepam is the most commonly used benzodiazepine for muscle spasm.167

Nitrous Oxide/Oxygen Mixtures

Nitrous oxide/oxygen mixtures can be used in the ED or the out-of-hospital care setting to reduce anxiety in patients and to manage mild to moderate pain states. The analgesic and anesthetic properties of nitrous oxide were discovered more than 200 years ago. Combined with oxygen, a mixture of nitrous oxide and oxygen in a 50:50 ratio is safe when self-administered by the patient. This technique is one of the original forms of patient-controlled analgesia. Nitrous oxide and oxygen administered by nasal mask have long been used by dentists. Experience in emergency medicine with nitrous oxide/oxygen mixtures has been greatest in the ratio of 50:50 with self-administered hand-held masks.168,169

The actual mechanism of analgesia and anxiolysis is not fully delineated, but it is known to diffuse through tissue membranes and is poorly soluble in blood. In the two-tank self-administered system, a fixed-ratio nitrous oxide/oxygen mixture is delivered to the patient through a demand valve activated when the patient inhales through a face mask or mouthpiece. A pressure of 3 to 5 cm H2O must be produced within the mask or mouthpiece to activate the flow of gas. This element provides safety for the patient-controlled aspects of the system since patients must initiate a breath and hold the mask to their face to receive the medication.

In 10 to 15% of patients, nitrous oxide is ineffective.168 It is much more potent as an anxiolytic than as an analgesic agent. As with all analgesic agents, its success should be determined by the patient’s subjective feedback. When necessary, nitrous oxide can be supplemented with other analgesics.

Nitrous oxide/oxygen mixtures are relatively or absolutely contraindicated in patients with a decreased level of consciousness who are unable to follow instructions, patients with a head injury, or those with decompression sickness. Patients with severe chronic obstructive pulmonary disease who retain CO2 should be given nitrous oxide/oxygen mixtures carefully because the mixture contains 50% oxygen. Because nitrous

GABA, γ-aminobutyric acid.
Local anesthesia

Mechanism of Action

Peripheral nerves are responsible for transmitting pain information from the pain receptors to the spinal cord. Each fiber consists of an axon surrounded by a covering called the Schwann cell. A myelinated axon is one that is covered by the projection of a Schwann cell that wraps itself many times around the axon, which is called the myelin sheath.

Local anesthetics are much more effective at penetrating unmyelinated or lightly myelinated fibers than heavily myelinated ones. This differential explains the fact that ordinarily unmyelinated or lightly myelinated fibers than heavily myelinated ones. This differential explains the fact that ordinarily

Classes of Local Anesthetic Agents

Local anesthetic agents are chemical compounds that consist of an aromatic and an amine group separated by an intermediate chain. The class that has an ester link between the intermediate chain and aromatic portion is called amino esters and includes procaine, chloroprocaine, and tetracaine. Amides have an amide link and include lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. Esters are unstable in solution and are metabolized in the body by the plasma enzyme cholinesterase. The amides, after absorption into the body, are destroyed by enzymes in the liver.

Specific Agents

Each local anesthetic has a predictable effect when used in appropriate doses and by the appropriate route. The main considerations in the clinical use of these agents are potency, duration of anesthesia, and the speed of onset (Table 186-7).

Potency. The ability of a local anesthetic drug to penetrate the lipid membrane of the axon determines its potency. Agents that have a high lipid solubility (e.g., tetracaine, etidocaine) are more potent than those with a low lipid solubility (e.g., procaine, mepivacaine). Less potent local anesthetics must be given in more concentrated forms and in larger doses to achieve an equivalent effect.

Duration of Anesthesia. Agents that bind well to protein in the sodium channel are longer acting and provide anesthesia of long duration. Tetracaine and bupivacaine have a high affinity for protein and provide long-lasting anesthesia, whereas procaine, which is poorly bound, does not.

Onset of Action. In most cases, it is helpful to have an anesthetic agent that acts quickly. The speed of onset of any local anesthetic agent is directly related to how quickly that agent, after injection, can diffuse through tissues to the nerve and through the nerve membrane. After injection, the agent is in two forms, ionized and nonionized. The amount of drug in the nonionized form is determined by its pKₐ (the pH at which 50% of the solution is nonionized and 50% is ionized). Because only the nonionized form of the drug diffuses into the nerve, solutions with a low pKₐ have a more rapid onset of anesthesia. Local anesthetic agents with higher pKₐs take effect more slowly. At a tissue pH of 7.4, 5% of tetracaine (pKₐ 8.5) is in the nonionized form compared with 35% of lidocaine (pKₐ 7.9) solution. Low tissue pH (5 or 6) in surrounding infected tissue delays the onset of local anesthesia in situations such as abscess incision and drainage, because the anesthetic primarily remains in an ionized state. The onset of action of a local anesthetic can be hastened by the alkalinization of the solution carrying the drug, which also decreases its irritant effect (pain) on injection. This can be done by adding sodium bicarbonate solution to the anesthetic at a ratio determined by the pKₐ of the agent (e.g., 1:10 for lidocaine).

Several other factors influence the clinical performance of local anesthetic agents. In the clinical dosages used, these agents (except cocaine) are vasodilators, which tend to shorten the duration of anesthesia. Injection of the solutions into vascular tissues not only shortens the duration of anesthesia but also increases systemic absorption and the (small) chance of systemic toxicity. For these reasons, epinephrine is often added to local anesthetic solutions.

*All maximum doses should be reduced 20–25% in very young, old, and very sick patients.
†A lidocaine level of 0.5–2.0 µg/mL may be reached for every 100 mg of lidocaine infiltrated for blocks.
‡Epinephrine adds to the potential cardiac toxicity of this drug.
§Not to be used for pudendal blocks or intravenous regional anesthesia. Not recommended for children younger than 12 years old.

Box 186-5

Techniques That Can Be Used to Reduce the Pain of Injection

- Buffering of local anesthetic agents
- Counterirritation
- Slowing rate of injection
- Use of topical anesthetics
- Warming solution
- Distraction techniques

Reducing the Pain of Injection

Counterirritation by scratching, jiggling, or repetitively pinching the skin during needle puncture or injection reduces discomfort (Box 186-5). The addition of sodium bicarbonate to lidocaine immediately before injection significantly reduces patient discomfort. A standard solution of sodium bicarbonate (8.4% in 50 mL) can be added to a syringe containing lidocaine in a ratio of 1:10 (e.g., 1 mL bicarbonate to 10 mL lidocaine, or 0.5 mL to 5 mL). Buffered lidocaine can be stock in the ED and is effective for up to 1 week. Bupivacaine can also be buffered, but the ratio should be 1:50 (i.e., 0.1 mL bicarbonate to 5 mL bupivacaine). Slow injection attenuates pain of infiltration to a greater degree than buffering of the solution. Injection of local anesthetic into the edges of the laceration is less painful than injection through intact skin surrounding the wound. When time permits, warming the anesthetic or the application of a topical anesthetic agent can also greatly decrease the initial sensation associated with needle injection.
Topical Anesthesia

Topical anesthetics are generally of two types: those that can be applied to intact skin and those used on open skin. The agents are absorbed and exert their anesthetic effect on adjacent superficial nerves. The topical application of local anesthetics must be done with just as much caution as used with injected anesthetics to avoid systemic toxicity. The dose of topical anesthetic should be monitored to avoid applying doses associated with toxicity. As with injectable local anesthetic agents, topical solutions are often described in terms of percent of agent; 1% equals 10 mg/mL of anesthetic, and 5% solution has 50 mg/mL.

Topical agents are particularly useful in children and in patients who are afraid of needles. They don’t provide anesthesia to the same degree as SC infiltration or nerve blocks but provide a substantial decrease in the intensity of superficial stimuli. The long application time necessary for effective analgesia can be a principal drawback of these agents; however, in some patients the ritual of applying the topical anesthetic and delaying the procedure until there will be less pain can be an effective tool in controlling pain and the response to subsequent interventions.

Topical Anesthetics Applied to Intact Skin

Eutectic Mixture of Local Anesthetics. Eutectic mixture of local anesthetics (EMLA) is a mixture of lidocaine and prilocaine in an alkaline oil mixture in which the anesthetics occur primarily in their nonionized form, allowing them to diffuse through the skin. The term eutectic refers to mixtures that result in a melting point higher than that of either agent alone. The mixture should be applied on the desired area with an occlusive dressing 30 to 60 minutes before the desired procedure is performed. Heating the EMLA for 20 minutes improves analgesia but is less effective than a routine 60-minute application with or without heat.186 The duration of action after a 60-minute application is 1 to 5 hours. Indications for the use of EMLA include venipuncture, arterial puncture, lumbar puncture, or arthrocentesis when a 30- to 60-minute delay in performing the procedure is not an impediment. EMLA can be applied in triage, particularly for pediatric patients, whose IV can then be started later in the ED with little or no pain.

Ethyl Chloride and Fluori-Methane sprays. Ethyl chloride and fluorimethane sprays are occasionally used for superficial analgesia. The agents evaporate quickly and cool the skin, providing brief (<1 minute) local anesthesia due to the cold. The induced analgesia is brief, and any injection or incision should be made immediately after the application of the agent causes a brief “frosting” effect in which the skin blanches white.

Agents Applied to Mucosal Surfaces

Cocaine. This agent is unique among local anesthetic agents because it is a potent vasoconstrictor in addition to being an anesthetic and can be applied to mucosal surfaces. It is frequently used in the nose, where a 4% (40 mg/mL) solution provides rapid anesthesia for the treatment of epistaxis and other procedures on the nose. Although the maximum safe dose is unknown, more than 200 mg should not be exceeded in adults. Cocaine should not be used in patients with known coronary artery disease because it may cause coronary artery vasoconstriction.

Lidocaine. Both 2 and 4% solutions of this drug are available in a viscous matrix for use on mucosal surfaces. It can be used in nasal procedures, including the passing of nasogastric tubes and gastric lavage tubes. It can be used for urethral anesthesia during Foley catheter placement as well, but to be effective it must be injected in the urethra with a catheter-tip syringe and be in contact with the area for 5 to 20 minutes. Lidocaine spray (4%) decreases the discomfort of nasogastric tube insertion. Lidocaine spray (4 or 10%) is useful for upper airway anesthesia, including intranasal use.

Tetracaine. This potent ester is used for surface anesthesia of the cornea. It stings when placed in the eye, but only for 10 to 15 seconds, after which there is profound corneal anesthesia.

Benzocaine. Almost insoluble in water, benzocaine remains on mucous membranes in the mouth and is used commonly to provide superficial analgesia for oral procedures and pain.

Agents Applied to Open Skin

Tetracaine, Adrenaline, and Cocaine. The combination of tetracaine, adrenaline (epinephrine), and cocaine (TAC) was popular in the past but has been largely replaced with lidocaine, epinephrine, and tetracaine (LET), which does not contain cocaine. Between 5 and 10 mL of this combination of agents is applied to the open wound using sterile cotton, which is then covered and held in place for 10 to 20 minutes. Anesthesia has been described in approximately 85% of cases of wounds of the scalp and face and a lower percentage of extremity wounds.187 Application of the solution to mucous membranes (eye, intra-nasal) can result in toxic blood levels of both tetracaine and cocaine and should be avoided.188

Lidocaine, Epinephrine, and Tetracaine. LET is as effective and less expensive than TAC.189,190 To account for the 20-minute onset, one study showed success when the application was administered at the time of triage in children with a simple laceration.191

Intravenous Regional Anesthesia (Bier Block)

The IV regional anesthesia procedure known as Bier block is an effective and rapid technique to anesthetize extremities for fracture reduction or repair of extensive wounds. The method involves the IV injection of a local anesthetic agent (lidocaine, prilocaine) into a previously exsanguinated limb. This procedure has been adapted for use in the ED in the form of a minidose of 100 mg of lidocaine and is described in procedure manuals. A safe alternative is to use the relatively nontoxic local anesthetic agent prilocaine.

Nonpharmacologic Interventions

Transcutaneous Electrical Nerve Stimulation

TENS systems uses electrical stimulation to induce analgesia, likely through the activation of descending sensory pathways and modulation of nociceptive signals at the level of the spinal cord. TENS units include a pulse generator, amplifier, and electrodes. Studies show varying degrees of effectiveness, and the devices are rarely, if ever, indicated for use in the ED.192,193

Hypnosis

The induction of hypnosis allows patients to refocus attention away from pain and anxiety-producing stimuli to other images and feelings. Hypnosis can be used as an adjunct to pharmacologic interventions or, in some cases, as a substitute. Hypnosis can be induced with only brief interventions on the part of the clinician.194,195 Hypnosis is usually not possible in the ED because of time constraints and distracting ambient noise.
Pain Management in Children

Pain in children is both more difficult to assess and more challenging to treat. When used properly, most of the interventions described in this chapter can be used in children. The same general principles that apply to providing analgesia to adults apply to children. The major difference in providing analgesia to children is the difficulty of accurately assessing the perception of pain, particularly in the very young.196

The general approach to a child can be important in developing a trusting relationship with both child and parent. Both verbal and nonverbal cues from the child and parents must be observed and appreciated, taking into account the unique developmental aspects of each age group. Threatening equipment should be de-emphasized (e.g., syringes, scissors, and suture holders should be kept out of sight of the child). Play therapy and a slow, friendly, nonthreatening manner can be helpful. The decision to separate children from their parents must be individualized but should be avoided when possible. Parents can help distract the child and reinforce the suggestions of the medical team.197

Most of the principles relating to the pharmacokinetics of drugs, including absorption, distribution, and elimination, are similar for children and adults. In neonates and infants younger than 3 months old, opioid clearance is delayed, plasma drug levels are higher due to decreased protein binding, and the blood-brain barrier is immature and more permeable to opioids. Opioids must be given carefully to this age group and at smaller weight-based doses than used in older children. Neonates also require smaller doses of local anesthetics due to decreased protein binding and slower metabolism. For mild pain, acetaminophen can be very effective in doses of 15 mg/kg PO or 20 mg/kg PR every 4 hours. Sucrose solutions have been shown to be effective agents in this age group, 25% applied to a pacifier and given PO.

Pain Management in Elder Patients

Approximately 80% of elder patients have at least one chronic ailment commonly associated with pain.198 Elders are more sensitive to analgesics, especially opioids, and reduced dosing achieves adequate analgesia while avoiding side effects. Opioids, even in conservative doses, may produce sedation, confusion, or constipation, and the patient and caregivers should be alerted to this possibility. NSAIDs are used in reduced doses or avoided altogether because of their potential for adverse effects on GFR.

The assessment of pain in elder patients can be complicated by depression, dementia, and atypical patterns of pain presentation.199 As with children, careful attention must be paid to the assessment of pain in the elderly due to communication barriers.

Out-of-Hospital Analgesia

Out-of-hospital providers frequently encounter patients with painful conditions, and patients obtain pain relief more quickly when pain medications are started by out-of-hospital personnel.200 but pain control in the out-of-hospital setting is challenging to perform adequately.203-206 Protocols for the administration of fentanyl and morphine exist in most EMS systems and are usually limited to single-dose therapy prior to obtaining orders from the medic control physician.204 No difference in the relative value of using fentanyl or morphine is found.205

The out-of-hospital environment is less controlled than the ED, and the information about a patient's underlying condi-

TREATMENT ENDPOINTS

Pain is a subjective experience, and using pain relief as the endpoint of treatment results in a subjective marker of treatment success or failure. In the ED, management of acute pain should target a specific desired endpoint; for example, reduction of the patient's self-reported pain score to 3 or less, or by 50% of the starting level. Pain medication, usually IV opioids, is ordered by frequent titration to reach that specific endpoint, usually with a caveat regarding total dose that might prompt a reorder. For example, “morphine sulfate 10 mg IV loading dose, then morphine sulfate 5 mg IV every 10 minutes until the patient reports pain as 3/10 or less. Please notify me if more than 30 mg administered in any 60-minute period.” This allows the nurse to titrate the medication to the patient's pain and to feel comfortable that he or she knows when to alert the clinician that the patient is requiring larger than anticipated doses. Pain orders that are wide-ranging or vague should be avoided, because they frequently lead to underdosing and inadequate pain relief. An example of such an order is “morphine sulfate 6 mg IV now, and repeat 2 to 6 mg IV every 20 to 40 minutes as needed for pain.”

KEY CONCEPTS

- Patient pain should be rapidly relieved and frequently reassessed in tandem with diagnostic evaluations.
- Titrated IV opioid analgesics are the principal therapeutic approach to the treatment of moderate and severe acute pain; the IM route has several disadvantages and is not recommended.
- Morphine, fentanyl, and hydromorphone are the preferred agents for the majority of opioid indications in the ED.
- There is no validity to the belief that morphine causes more smooth muscle spasm than other opioids and should be avoided in patients with biliary or renal colic.
- Topical and local anesthetics can be used to treat pain associated with the majority of ED procedures and should be considered for use in all isolated painful conditions.
- Low tissue pH (5 or 6) in infected tissue delays the onset of local anesthesia.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The performance of painful diagnostic and therapeutic procedures is common in emergency care. Many of these are associated with significant anxiety, especially in children. Procedural sedation and analgesia (PSA) has therefore become a fundamental and required skill for emergency physicians and an integral part of the core training of emergency medicine residents.

PSA improves the quality of patient care and satisfaction through relief of pain and anxiety and by facilitating the success of therapeutic or diagnostic procedures. These include fracture or joint reduction, incision and drainage of abscesses, cardioversion, tube thoracostomy, lumbar puncture, complex wound repair and imaging studies in young or uncooperative patients.

Many of the agents used for PSA have the potential to cause significant respiratory, cardiovascular, or central nervous system (CNS) depression. The Joint Commission, the American College of Emergency Physicians, and the American Society of Anesthesiology have produced expert consensus or evidence-based documents concerning its use. With the advent of these guidelines, PSA has become a safe, common, and practical emergency department (ED) procedure. This has been further improved by the development of shorter-acting, more effective drugs and the utilization of noninvasive monitoring devices.

With the wide variety of procedures and patient populations, the ability to individualize PSA and maximize the risk-benefit ratio for each unique situation is a necessary skill. This can be best achieved through a detailed understanding of: the preprocedural patient assessment, the protocols delineating the required personnel and their roles, the supplies and equipment required, the specific drugs used (including their routes of administration, dosages, effects, interactions, and complications), consideration for special populations and patient monitoring, recovery, and discharge criteria.

Terminology

Anxiolysis is a state of decreased apprehension concerning a particular situation in which the patient’s level of awareness does not change.

Analgesia refers to the relief of pain without the intentional alteration of mental status, such as occurs in sedation. An altered mental state may be a secondary effect of the medications administered for this purpose.

Dissociation is a trancelike cataleptic state induced by an agent such as ketamine and characterized by a profound analgesia and amnesia. Protective reflexes, spontaneous respirations, and cardiopulmonary stability are retained.

Sedation is a controlled reduction of environmental awareness.

Procedural sedation and analgesia is a technique of administering a sedative or dissociative agent, usually along with an analgesic, to induce a state that allows the patient to tolerate unpleasant procedures while maintaining adequate spontaneous cardiorespiratory function. It is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously. The drugs, doses, and techniques used are not likely to produce a loss of the protective airway reflexes.

Prior terminology defined three levels of sedation: conscious sedation, deep sedation, and general anesthesia. The term conscious sedation was often misinterpreted, confusing, and imprecise. It was coined in 1985 to describe lightly sedated dental patients. It was then further incorporated into pediatric sedation guidelines to distinguish an easily arousable level of sedation from the more advanced techniques of deep sedation, in which patients are difficult to arouse, or general anesthesia, in which patients are not arousable. Despite the focused intent of these definitions, practitioners quickly labeled all levels of procedural sedation taking place outside the operating room as “conscious sedation.”

In 2001, The Joint Commission adopted the American Society of Anesthesiologists (ASA) definition of sedation and analgesia that was created in 1999 to better describe the continuum of sedation and analgesia (Fig. 187-1). Although this truly is a continuum, the ASA divided PSA into four distinct subgroups. These include minimal sedation, moderate sedation, deep sedation, and general anesthesia. A fifth category, dissociative sedation, has since been added. This new nomenclature is more intuitive, clear, and logical.

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive functions and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate sedation (formerly called “conscious sedation”) refers to a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either
The progression from minimal sedation to general anesthesia truly is a dynamic continuum that lacks distinct separation between stages. The transition from one level of sedation to the next is often difficult to predict and varies from patient to patient. The sedation continuum is not drug-specific, and levels from mild sedation to general anesthesia can be achieved with virtually all of the PSA agents. Because of this, it is recommended that clinicians administering PSA be competent in the skills required to treat patients in a least one level greater than the intended level of sedation.

**Approach to Procedural Sedation and Analgesia for Procedures**

**Patient Assessment**

To date, no outcome-based studies have demonstrated clear benefit from extensive evaluation beyond vital signs, mental status, and airway and cardiopulmonary assessment prior to PSA. Despite this, consensus guidelines suggest that an increased risk of adverse events may exist in select subsets of patients. These include the extremes of age, patients with difficult facial or neck anatomy or any other reason for potential intubation or bag-valve-mask ventilation difficulty, and patients with underlying significant disease states. A patient’s general physical status is conventionally categorized according to the ASA’s classification system (Table 187-1). Most practice guidelines require that a history and focused physical examination be performed and documented prior to PSA. There is no literature to support the need for routine diagnostic testing other than diagnostic testing driven by the patient’s current status, including comorbidities.

The patient’s age; current illness or injury for which the PSA is intended; underlying medical problems (comorbidities); previous experiences or problems with PSA or general anesthesia; drug allergies and current medications; and tobacco, drug, and alcohol use are reviewed and recorded. A directed physical examination focuses on the vital signs, the heart and lungs, and evaluation of the airway for potential difficulty providing bag-valve-mask ventilation or intubation.

A discussion including the risks, benefits, and potential side effects of PSA should take place with patients or their families before the procedure. Written consent is obtained, unless this is not possible. Patient selection is important to the safety of the sedation. Not every patient is an appropriate candidate for PSA in the ED. Depending on the clinical circumstances, a patient with an anticipated difficult airway or an ASA classification of III or IV may require consultation with an anesthesiologist. It may be advisable in some cases to have the anesthesiologist perform the sedation or to undertake the...
procedure in the operating room under more controlled circumstances.

Preprocedural Fasting

The need for preprocedural fasting in PSA remains controversial. Currently the ASA recommends a period of 2 hours following ingestion of clear liquids and a period of 6 hours following the ingestion of other liquids or solids prior to PSA, but there are no outcome studies to support these recommendations. These guidelines are based on expert consensus and extrapolated from data describing circumstances when patients received sedation to the level of general anesthesia followed by the manipulation of their airway during intubation and extubation.20 PSA in the ED attempts to avoid both of these specific situations.

Many studies fail to support the notion that gastric emptying has any effect on the incidence of complications or outcome with PSA.20-29 There have been no published studies demonstrating an increased risk of aspiration following a liquid or solid meal and no studies showing a benefit of fasting prior to PSA. In one prospective observational study of more than one thousand children, no differences with airway complications, emesis, or other adverse effects were observed between various groups of patients classified by their preprocedural fasting status.27 During PSA, the combination of vomiting and the loss of the airway protective reflexes is an extremely rare occurrence. Furthermore, most episodes of vomiting and aspiration occur during airway manipulation, which is also very unlikely to occur during PSA. The issue of the risk of free reflux during deep sedation has not been well studied.

Although recent food intake is not a contraindication for administering PSA, risks of pulmonary aspiration and the benefits of providing PSA are weighed in accordance with the needs of each individual patient.5,30 Some procedures, such as reduction of a dislocated joint, should not be delayed for consideration of fasting status, while others, such as abscess drainage, are not as time-sensitive, and the sedation plan can be adapted accordingly.

Personnel

The Joint Commission and most institutional policies suggest that PSA providers have: adequate training to administer the agents effectively and safely, the skills to monitor the patient’s response to the medications given, and the expertise needed to manage all potential complications.5,36 Some procedures, such as reduction of a dislocated joint, should not be delayed for consideration of fasting status, while others, such as abscess drainage, are not as time-sensitive, and the sedation plan can be adapted accordingly.

Supplies and Equipment

Procedural sedation and analgesia may result in an allergic reaction, oversedation, respiratory depression, or, rarely, cardiopulmonary arrest. The incidence of these complications depends on patient selection, the drugs used, the rate and dosage of administration, and specific patient sensitivities. Consequently, appropriate equipment to monitor the patient’s condition at all times; to manage airway complications, allergic reactions, and drug overdoses; and to treat respiratory or cardiopulmonary arrest should be readily available. Supportive equipment must include oxygen, suction, patient-monitoring devices, basic and advanced airway management equipment, a monitor/defibrillator/pacer, advanced life support medications, reversal or rescue agents, and vascular access equipment (Box 187-1).

In most situations, the agents used for PSA in adult patients should be administered intravenously. Nearly all adults undergoing PSA in the ED should therefore have an intravenous (IV) line placed prior to the procedure. This need in children is less clear and depends on the presence of comorbid conditions and the choice and route of drug to be administered. If the procedure is likely to be lengthy, or if multiple doses of drugs will be needed, an IV line should be considered.

The requirement for supplemental oxygen, and its benefits during PSA, have not been well studied and remain somewhat controversial. Supplemental oxygen may prevent hypoxemia in many patients; however significant respiratory depression in these patients may not be detected because of their normal oxygen saturation. This may delay the recognition of respiratory compromise and hypercarbia.31-34 On the other hand, transient hypercarbia is not harmful, and maintenance of adequate oxygen saturation is much more important. The use of capnography eliminates this issue, because ventilatory status is displayed continuously (see following section). Because there are little scientific data to guide the clinician, the use of supplemental oxygen should be in accordance with institutional protocols and at the discretion of the treating physician. In general, though, there is little to advise against the use of supplemental oxygen when administering PSA to a patient in the ED.

Monitoring

The most important aspect of monitoring during PSA is the visual observation and assessment of the patient. The patient’s ability to follow commands in response to varied levels of stimulation is useful in quantifying the level of consciousness. Furthermore, the patient’s ventilatory status may be readily

*Suggested, not required ECG, electrocardiogram.
Pulse oximetry is a reliable and important monitoring adjunct, but it does not obviate the need to observe the patient. There is no evidence that cardiac monitoring during PSA is of any benefit. In older patients, or in those with a history of cardiovascular disease, hypertension, or dysrhythmia, the use of continuous electrocardiographic monitoring is advised. Capnometry or capnography measures end-tidal CO₂ partial pressure and may be useful to detect cases of inadequate ventilation earlier than with oximetry and prior to the onset of hypoxemia. Studies have demonstrated that this, but none have shown an effect on outcome to date. Although the benefit of adding capnometry to oximetry and visual monitoring remains unclear, it is well described in the anesthesia literature and may be considered useful when direct patient observation is difficult or impossible or when supplemental oxygen is being administered. Capnography should be used when deep sedation is planned, as respiratory depression is common in patients undergoing deep sedation.

The Bispectral index (BIS) is monitored via a noninvasive device attached to the patient’s forehead and derives a depth of sedation level via frontal lobe electroencephalographic measurements. It has been used in the operating room as an objective measure of sedation depth. Studies have shown that it may be beneficial in preventing oversedation in PSA and reducing the time to discharge. These investigations have also suggested that its use may better guide the depth of sedation endpoint than traditional sedation scales have, and it may have further benefit for PSA in children as they frequently require deeper levels of sedation to prevent movement. Early ED studies for its use in PSA to discriminate between mild-to-moderate and moderate-to-deep levels of sedation have not been reliable nor has it been shown to be predictive of patients sedated to the point of general anesthesia from those with lesser degrees of sedation. BIS monitoring may have a beneficial role for emergency medicine use and PSA in the future, but requires more investigation before its possible uses and benefits can be completely defined.

If it is necessary to transfer the patient outside the ED, every attempt should be made to provide the same level of monitoring during the transport that was used within the department.

The highest risk of serious adverse events generally occurs within 5 to 20 minutes of receiving the last dose of IV medication and at the completion of procedures, when the patient remains sedated but is no longer receiving the painful stimulus. Patients should continue to be monitored most closely at these times, and this should continue until clinical recovery has occurred (see following section).

Recovery

Monitoring as part of the PSA routine should continue until patients are spontaneously awake and able to function independently, even though they may not be completely back to baseline function or ready for discharge. Drowsy patients should not be left unattended, particularly when they are in other areas of the hospital. If patients are transported out of the ED before they have completely returned to baseline function, a trained caregiver with appropriate monitoring equipment and resuscitative supplies must accompany them.

Discharge Criteria and Instructions

Prior to discharge, a normal mental status and baseline cognitive and motor function should be achieved. The patient should be able to follow commands, speak clearly, and ambulate or sit unassisted (infants). Vital signs and respiratory status should be back to baseline and within normal limits. Residual pain should be addressed. Nausea should be minimal, and vomiting should be resolved. It is preferable that all patients, including adults, be sent home with a responsible adult, but if this is not possible, the patient must remain in the ED until normal baseline has been achieved.

Patients should be advised not to drive or participate in other dangerous activities for 12 to 24 hours. Despite the short clinical duration of most of the agents used, many people may exhibit subtle signs of cognitive deficits and mild drowsiness. It is therefore preferable that they be accompanied by a responsible adult at home for 4 to 8 hours. For children, light play at home should be the extent of activities with no bicycle riding, swimming, or other complex motor activity until the next day. An antinauseant and progressive diet is helpful if nausea or vomiting is experienced. Standard discharge instructions should also be provided for the presenting complaint and all should be instructed to immediately return if any confusion or respiratory symptoms arise.

Pharmacology

In selecting agents, one must consider the effects desired, the risks and benefits, and the logistics of administration for each situation. The ideal agent would provide analgesia, anxiolysis, amnesia, and somnolence. It would have a rapid onset and offset with predictable results and have no adverse effects. This agent, of course, does not exist.

When the procedure is unpleasant, but not painful (e.g., endoscopy), pure sedation may be the desired endpoint, and agents such as benzodiazepines, barbiturates, etomidate, or propofol sometimes are used alone. These agents do not provide pain relief and should not be used as the sole agent when pain management is also desired. Analgesic agents such as opioids or nitrous oxide are often added to a sedative agent to provide analgesia for painful procedures. Ketamine, on the other hand, may be an excellent single drug choice for painful or stimulating procedures in children and for some adult applications (e.g., fracture reduction). Usually, a combination of analgesic and sedative agents is required. One must be cautious as their side effects are frequently potentiated.

The specific agents for PSA and dosage recommendations for adult patients are provided in Table 3. Benefits and adverse effects are provided in Table 4. Individual agents are discussed in greater detail in the following sections.

Route of Administration

Route of administration should also be determined by the procedure and the specific patient. In most situations, IV titration to the desired level of sedation and analgesia provides the safest, most rapid, and most predictable results. Drugs given by the intramuscular (IM), oral (PO), transmucosal (TM), intranasal (IN), or rectal (PR) route generally have a slower onset of action, are difficult to titrate, have unpredictable results, and may lead to prolonged sedation. These routes are virtually never used for PSA in adults. In children, however,

Ketamine has been shown to provide consistent and predictable results when given IM. Nitrous oxide has predictable behavior when used as an inhalational PSA agent in children but is also usually used as an analgesic adjunct to a sedating agent. In pediatric patients, the benefits of IV drug administration may be outweighed by the difficulty and distress to the patient in obtaining IV access. In this situation, drugs given by the alternative routes may be preferred.

Drugs should be administered by titrated slow IV bolus to minimize hypotension or respiratory depression in many situations. Lower initial doses should be chosen in sensitive patients or when drugs from multiple classes are being administered. It is important to allow adequate time between doses to achieve and assess peak effect before a further dose is given.

**Opioids**

Parenteral opioids are commonly used as analgesics before performing painful procedures. For PSA, an opioid is rarely optimal as a single agent, and most clinicians combine an opioid with a sedative-amnestic agent to balance sedation-amnesia and analgesia with the least likelihood of respiratory depression. The most commonly used opioids in the ED for
PSA are fentanyl and morphine. These are often combined with benzodiazepines such as midazolam for moderate sedation and used in smaller doses to provide analgesia during deep sedation with etomidate or propofol. Meperidine historically was used for PSA but is no longer recommended because seizures are commonly associated with the accumulation of its long-lasting metabolite, normeperidine.

**Fentanyl**

Fentanyl has many advantages as an analgesic agent for PSA, given its rapid onset of action, short duration of activity, lack of histamine release, and favorable cardiovascular profile. Fentanyl rapidly crosses the blood-brain barrier and produces analgesia in as little as 90 seconds. Serum levels rapidly decline for peak concentrations because of extensive tissue uptake and glottic spasm, which may make ventilation difficult, are rare but may occur with high doses. Chest wall rigidity and glottic spasm, which may make ventilation difficult, are unique complications seen with very high doses (anesthetic) of fentanyl given rapidly (generally > 15 µg/kg). Many of these adverse effects may be readily reversed by naloxone. The exception to this is chest wall rigidity, which may not reliably be antagonized and may require neuromuscular blockade and intubation to enable adequate ventilation. This complication is very rarely reported with the dosages of fentanyl used for PSA.

</table>

CV, cardiovascular; ICP, intracranial pressure; IM, intramuscular; IN, intranasal; IOP, intraocular pressure; IV, intravenous; PO, oral; PR, rectal.
In children, PO TM fentanyl has been used widely as a premedication for anesthesia and IV placement. It has also been used for PSA when IV access is not feasible. This is generally in the form of a fentanyl-impregnated, sweetened matrix in lozenge form on a holder; the fentanyl lollipop. Transmucosal delivery allows rapid onset of action by avoiding first-pass metabolism in the liver. It has been shown to decrease activity and relieve pain in 10 to 30 minutes with scores similar to comparable IV doses of fentanyl. Despite this fairly rapid onset, TM delivery does not allow for easy titration. The general dosage is 10 to 15 μg/kg. Larger doses have been shown to cause more nausea and vomiting without improving analgesia or activity scores. The combination of TM fentanyl and TM midazolam has not been shown to have additional benefit over either agent used singularly for laceration repair in the ED and has been shown to increase adverse events. Its use prior to other agents such as propofol has not been studied well. The use of TM fentanyl for PSA has largely been limited by unacceptable levels of nausea and vomiting, which approach 20 to 40% of patients.

Morphine

Morphine is poorly lipid-soluble and penetrates the blood-brain barrier more slowly after small bolus injections. Ten to 30 minutes is required before its peak effects are seen, although when used for PSA, morphine performs in similar fashion to fentanyl, with comparable recovery times. A general starting dosage of 0.1 mg/kg is commonly used and then titrated to desired effect as with fentanyl (see preceding section). Morphine has much more histamine release and therefore is more likely to produce hypotension, especially in preload-dependent patients. It has similar potential to other opioids for producing respiratory depression, especially when used with other CNS depressants such as benzodiazepines. Morphine undergoes hepatic metabolism to an active metabolite followed by renal excretion. Insufficiency of either organ system may lead to increased serum half-life.

Benzodiazepines

Benzodiazepines are potent amnestic, hypnotic, and anxiolytic medications. They also have anticonvulsant and purported muscle relaxant properties but do not have analgesic effects. Because of this, they are commonly coadministered with an analgesic agent such as fentanyl or morphine. They may be given IV, IM, PO, IN, or PR but are virtually always used via IV for PSA in adults. Midazolam is the most commonly used agent, because of its favorable pharmacokinetics.

Midazolam

Midazolam has many advantages for PSA given its rapid onset of action and short duration of activity compared with other benzodiazepines. Its amnestic properties also appear to be superior to many of the others. The starting IV dose is 0.05 mg/kg. Children may need slightly higher doses. Onset of sedation is generally within 1 to 2 minutes, and the duration of action is 30 to 60 minutes. Alternatives to the IV route are often used in children, particularly when sedation alone, without analgesia, is desired as for performance of a radiologic study. With IM administration the same doses may be used, but the onset of duration is delayed. Oral doses are often used in children, with a recommended starting dose of 0.5 mg/kg. Sedation is generally achieved within 30 minutes. Rectal administration may also be useful with doses of 0.5 mg/kg. The response by this route may be less predictable, and it is generally not accepted by older children. Intranasal administration may be useful but is irritating and often difficult in older children as well. The starting dose for this route is 0.2 mg/kg and results in sedation in 10 to 15 minutes. Of note, 1% of children younger than 5 years may experience a paradoxical reaction and become excited and agitated when given midazolam. If necessary, the agitated state is reversible by flumazenil. Midazolam has been shown to be an extremely safe and effective agent for PSA, both alone and when used in combination with fentanyl.

Side effects include dose-dependent hypventilation and hypoxemia. Apnea and hypotension are uncommon, but occur more often at high doses or when other CNS depressants such as opioids are used. Headache, nausea, emesis, coughing, and hiccups have been shown to occur, although rarely. Lower doses should be used when other agents such as analgesics are given concomitantly and in the elderly. Prolonged effects may be seen in elderly patients or those with liver dysfunction due to decreased hepatic or first-pass metabolism. Midazolam is highly lipophilic and its effects may be greatly amplified in obese patients, resulting in an increased plasma half-life of up to 8 hours with high or repetitive doses. Chronic alcohol users who do not have liver dysfunction may require relatively high doses of midazolam to achieve the same clinical effects.

Barbiturates

Barbiturates are also potent hypnotics, with amnestic and anti-convulsant effects. They do not have analgesic properties. Before the widespread use of midazolam and the advent of propofol for deep sedation, barbiturates were commonly used for brief painless procedures, but they are much less commonly used now. They are not commonly combined with other agents, due to their narrower therapeutic window. The most useful barbiturate PSA agents are methohexital and pentobarbital. These drugs generally have a brief procedural effect due to redistribution, but large or repetitive dosages may lead to significantly prolonged sedation due to their actual plasma half-life.

Methohexital

Methohexital is a highly lipophilic ultra-short-acting barbiturate with a rapid onset of amnesia and deep sedation in 30 to 60 seconds. It does not provide analgesia, and an opioid, such as fentanyl, is required for painful procedures. The concomitant use of fentanyl or another opioid increases the risk of apnea. Intravenous doses of 1 mg/kg produce unconsciousness for approximately 5 minutes. It may also be administered PR in children at a dose of 25 mg/kg but has a more variable effect and longer onset and duration of action. Depressed respiratory drive and apnea are more common than with other agents but are generally transient and mild. Most patients respond to supplemental oxygen and repositioning of the airway. Its use in the ED appears to be safe and effective, particularly for brief orthopedic joint reductions, cardioversions, and radiologic imaging procedures. Only a small percentage of patients require brief periods of assisted ventilation. In several studies, no ED patients have required intubation or change in disposition after receiving methohexital for PSA. Methohexital does have the potential to cause significant hypotension as well and should be used with caution in patients with hemodynamic instability or occult blood loss. It also may cause activation of the respiratory reflexes, inducing coughing, hiccups, and, rarely, laryngospasm. In contrast to the other barbiturates, methohexital may worsen or precipi-
cate seizures, and it is prudent to avoid it in patients with a known seizure disorder.\textsuperscript{130,132,133} Propofol has largely supplanted methohexital for PSA because it has more reliable, consistent effects, is easily titrated, and can be administered as an infusion for longer procedures.

Pentobarbital

Pentobarbital is also a barbiturate sedative agent, best used via IV for nonpainful diagnostic studies. Its onset of action is generally within 1 to 2 minutes, with a duration of 30 minutes. It is usual to start with an initial dose of 2 mg/kg and titrate to effect with subsequent doses of 1 to 2 mg/kg every 30 seconds as needed. The predominant complications with pentobarbital are respiratory depression, hypotension, and prolonged recovery.

Ketamine

Ketamine is a well-studied, safe, and predictable agent for use in the pediatric population for PSA.\textsuperscript{76,128,129,134,141} It is gaining popularity for use in adults as well.\textsuperscript{137,142,143} It is a derivative of the street drug phencyclidine and is classified as a dissociative agent. It causes disruption between the thalamo-neocortical and limbic systems, preventing the higher centers from perceiving visual, auditory, or painful stimuli. Due to this, its use leads to profound analgesia, amnesia, and catalepsy. It does not produce unconsciousness, but rather a trancelike state. Patients often experience nystagmus, roving eye movements, and random movements of the extremities unrelated to painful stimuli. Parents observing procedures in which ketamine is used may be disturbed at seeing this and should be forewarned.

Ketamine has several advantages over other PSA agents.\textsuperscript{76,126,129,135,144,145} The most notable are its profound analgesic effect and the lack of significant or frequent respiratory depression. The protective airway reflexes, such as coughing, swallowing, and muscular tone of the tongue and pharynx are well maintained or slightly enhanced. Its use further leads to blockade of catecholamine reuptake, and blood pressure is generally well supported. It also induces bronchial smooth muscle relaxation and is well tolerated in patients with reactive airway disease. It has a fast onset and offset and is predictable when given by the IV or IM route. Following administration, it is rapidly distributed and taken up by the cerebral tissues. The effects are maintained until the drug redistributes into the peripheral tissues and is metabolized by the liver. Due to this mechanism, repeat doses are well tolerated in longer procedures with predictable results.

Ketamine may be given by multiple routes but is used almost exclusively by the IV route in adults. Following an IV dose of 1 to 2 mg/kg, a dissociative state results in approximately 1 minute with duration of action of approximately 15 minutes. Complete recovery generally requires 1 to 2 hours. Similar cataleptic results may be seen with an IM administration of 4 to 5 mg/kg in approximately 5 minutes, with effects lasting 15 to 30 minutes. For pediatric sedation, ketamine is generally administered by the IV or IM route but may also be given PO (10 mg/kg), PR (10 mg/kg), or intranasally (6 mg/kg). These other routes are infrequently used due to variable onset of action, slow offset, and less predictable results.

The most common side effect seen with ketamine is the emergence phenomenon.\textsuperscript{134,140,141} This occurs in approximately 15% of patients and is mild in almost all. They may wake up with unpleasant, vivid dreams or hallucinations or complain of nighttime awakenings due to unpleasant dreams for several days following its administration.\textsuperscript{148-150} Less than 1 to 2% of patients have significant emergence agitation. This is more commonly seen in female patients, adolescents or adults, and in those with underlying psychiatric disorders. Its rare occurrence, especially in children, should not limit ketamine’s use when indicated. Some studies have suggested that preprocedural or concurrent administration of midazolam may mitigate this reaction, but others have disputed its utility. Some practitioners feel that a tranquil state and preprocedure pleasant imagery prior to drug administration may also be of benefit.\textsuperscript{137,138,140,148}

Other side effects seen with ketamine use are transient apnea, laryngospasm, and emesis.\textsuperscript{33,151} These are also rare but more common with rapid IV administration. Doses given slowly, at a rate of 0.5 mg/kg/min, may limit much of this. Ketamine also stimulates tracheobronchial and salivary secretions. Since airway reflexes are maintained, this generally isn’t a concern except in young children. In young children, and any patient undergoing airway examination (e.g., fiberoptic laryngoscopy), pretreatment with glycopyrrolate, 0.01 mg/kg given 10 minutes before the ketamine, may be beneficial. Postrecovery nausea and vomiting are also frequently seen but generally short-lived.

Significant laryngospasm has been seen in infants younger than 3 months and in children with upper respiratory tract infections. It is recommended that ketamine be avoided in these patients. Due to catecholamine-mediated hypertension and tachycardia, ketamine should also be avoided in those with significant cardiovascular or coronary artery disease. Ketamine also increases intracranial and intraocular pressure and should be avoided in those with significant head trauma, CNS abnormalities, or open globe injuries.

Etomidate

Etomidate is a short-acting sedative-hypnotic agent that is structurally unrelated to the other PSA agents and has no analgesic properties. Its use leads to the very rapid onset of profound sedation and hypnosis by enhancing neurotransmission at γ-aminobutyric acid receptors. Etomidate has been used for deep sedation because of its rapid onset, short duration of action, and, most importantly, minimal effects on respiratory and cardiovascular function.\textsuperscript{152-164}

Following IV administration, sedation occurs in approximately 1 minute, and patients recover in 5 to 10 minutes. Etomidate induces deep sedation that borders on general anesthesia with higher doses and may be more difficult to titrate than the other sedative hypnotic agents. It is generally administered IV, with an initial dose of 0.1 mg/kg given slowly over 1 to 2 minutes. Additional doses of 0.05 to 0.1 mg/kg may be administered every 2 to 3 minutes until the desired level of sedation is achieved. Smaller initial doses should be considered when it is combined with analgesic agents or in the elderly. Because it has little effect on the cardiovascular system and is cerebral protective, it is an excellent choice for patients who have the potential for hemodynamic instability or increased intracranial pressure.

Adverse effects that may limit its usefulness include apnea, respiratory depression, myoclonus, nausea, vomiting, and adrenal suppression.\textsuperscript{133,154,162,165-168} These side effects are more common with rapid IV administration, when higher doses are used, and in older patients. Although respiratory depression is rare and generally transient, few patients may require brief periods of assisted ventilation. Myoclonus is also typically described as mild and brief but at times may interfere with the procedure. Vomiting is unlikely with dosages administered in the ED. Etomidate suppresses adrenal function by inhibiting 11-β-hydroxylase activity. This is not a concern when a single sedating dose is used (see Chapter 1).\textsuperscript{169-173}
Propofol

Propofol is another short-acting sedative-hypnotic agent that is structurally unrelated to the other PSA drugs and has no analgesic properties. It has an extremely rapid onset, a short duration of action, and predictable efficacy for inducing deep sedation. Sedation quickly clears completely, permitting superior titration and earlier recovery and discharge. Propofol also possesses potent antiemetic properties and decreases intracranial pressure. It does not provide analgesia and is frequently preceded by an opioid for painful procedures. As with all sedative agents, the addition of an opioid may increase the risk of deeper than anticipated sedation, respiratory depression, apnea, and hypotension.

Propofol is administered by an initial IV bolus dose of 0.5 mg/kg that is then titrated every 3 to 5 minutes by 0.25- to 0.5-mg/kg aliquots to the desired sedation level. Children may require slightly higher dosing than adults. The onset of sedation occurs in less than 1 minute, and patient recovery is in 10 minutes. For procedures lasting longer than this, additional boluses of 0.5 mg/kg may be administered, or a continuous infusion of 3 to 6 mg/kg per hour may be titrated to the desired level of sedation. Smaller doses should be used when sedating elderly patients or when administering propofol with analgesics.

Adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Other agents such as opioids may intensify these effects. In most cases apnea is transient, and patients often respond to repositioning of the airway or, rarely, a brief period of assisted ventilation. Propofol commonly results in a transient drop of systolic and diastolic blood pressure, which generally responds to fluid administration and is well tolerated in healthy patients. When given by rapid bolus, or to patients with hypovolemia, this can be significant and should be avoided. Pain associated with propofol injection occurs in the majority of patients and can be reduced with small infusions of IV lidocaine under tourniquet prior to its administration.

Nitrous Oxide

Nitrous oxide is a gas that, when used in combination with oxygen, provides excellent analgesia to supplement procedural sedation. It diffuses rapidly across the alveoli in the lungs, providing a predictable and rapid onset in 1 to 2 minutes and rapid elimination in 3 to 5 minutes.

Nitrous oxide is administered as a 30 to 70% mixture with oxygen by a demand-valve mask or mouthpiece held by the patient. It must be administered with at least 30% oxygen to avoid hypoxemia. A 30% concentration may be less than effective for PSA, especially in children, whereas a 70% mix may result in the loss of protective airway reflexes.

The need for a scavenger device and proper ventilation exhaust have limited the use of nitrous oxide in the ED. Because nitrous oxide rapidly diffuses into gas-filled pockets, it can potentially worsen conditions such as pneumothoraces, small-bowel obstructions, decompression sickness, chronic obstructive pulmonary disease, and middle ear effusions. High concentrations may lead to nausea and vomiting, respiratory depression, and general anesthesia.

Reversal and Rescue Agents

Careful titration of PSA drugs to the desired level of sedation is the goal. At times, unanticipated deeper levels of sedation may be reached, and respiratory depression or apnea may be experienced. Airway repositioning, supplemental oxygen, and bag-valve-mask ventilation may be required. If these periods are prolonged, partial or complete reversal of agents such as opioids or benzodiazepines may be necessary. Elective reversal of PSA following the completion of the procedure is not recommended.

Naloxone

Naloxone is a competitive antagonist of opioids and has been effectively used for the reversal of opioid-induced respiratory depression during PSA. It has a rapid onset of action and a mean plasma half-life of approximately 45 minutes though its clinical effects last only 15 to 30 minutes. Resedation is generally not a problem for patients who have been given fentanyl or morphine in doses recommended for PSA. Nevertheless, these patients should be observed for a minimum of 1 hour after the administration of naloxone. It is especially important for patients who have received large doses of fentanyl to ensure that redistribution of fentanyl within the body does not result in the recurrence of sedation.

Naloxone may be administered IV, IM, subcutaneously, or via endotracheal routes, but is almost universally given via IV. The smallest dose necessary to restore respiratory effort should be used, because reversal of the opioid’s respiratory depressant effect is matched by reversal of the analgesia. Initial dosing depends on the patient and the specific goals desired. For partial reversal, titrated doses of 0.1 to 0.2 mg may be used every 1 to 2 minutes to desired effect. Complete reversal is almost never desirable and requires doses of 1 to 2 mg. Similar dosages may be used in children. In patients who are opioid-dependent these doses may precipitate an acute withdrawal state. Smaller initial doses should be considered. Large doses of naloxone may also make it more difficult to control postprocedure pain. Naloxone use has little risk, but pulmonary edema, seizure, and dysrhythmia rarely have been reported.

Flumazenil

Flumazenil is a competitive antagonist of benzodiazepines. Although it reverses the sedation effect of benzodiazepines, it is not as effective for reversing respiratory depression. In general, when oversedation occurs, brief support of ventilation permits the patient to recover sufficient spontaneous respiration without the need for reversal. Flumazenil has a rapid onset of action in 1 to 2 minutes, a peak effect in 5 to 10 minutes, and a half-life of 45 to 90 minutes. Continuous patient monitoring must be ensured when it is used to reverse respiratory depression associated with longer lasting benzodiazepines because resedation is likely. Flumazenil has also been shown to be effective in reversing paradoxical excitement in children.

It is generally titrated in doses of 0.1 to 0.2 mg IV every 1 to 2 minutes to the desired effect. A maximum dose of 1 mg is generally sufficient. Common pediatric doses of 0.02 mg/kg are generally used, with a maximum of 0.2 mg. It should be used with extreme caution in patients with benzodiazepine dependence or a history of seizures as it may precipitate life-threatening status epilepticus. Routine reversal is not recommended.

Drug Selection and Administration

When choosing a strategy for PSA, it is important to consider the type of procedure being performed (painful or not), the length of the procedure, specific procedural requirements (anxiolysis vs. immobility), and whether sedation may need to be prolonged. The need for IV access generally is an issue only
in small children. Planned adjuncts, such as topical, local, or regional anesthesia are also considered. Patient factors, including age, medications, alcohol and drug use, and comorbid conditions are considered when selecting both the agent and the initial dose. Procedures needing sedation may be broadly divided into three categories: nonpainful procedures requiring immobilization (e.g., computed tomography, magnetic resonance imaging), low-pain high-anxiety procedures (e.g., laceration repair, lumbar puncture), and highly painful high-anxiety procedures (e.g., fracture or joint reduction, tube thoracostomy, abscess drainage, cardioversion). These are summarized in Table 187-5 for adult patients and Table 187-6 for pediatric patients.

For brief nonpainful procedures requiring complete immobilization, IV midazolam, etomidate, and methohexital are excellent initial choices. For longer procedures, PO midazolam, PR methohexital, or IV pentobarbital may be indicated. Intravenous propofol should also be considered and may become the agent of choice as its use becomes more commonplace in the ED. Nitrous oxide may be an alternative if complete immobilization is not required.

For briefly painful procedures requiring minimal to moderate sedation and where topical or local anesthetics may be used (e.g., reduction of a glenohumeral dislocation for which intra-articular lidocaine will be used), midazolam is a reliable and safe choice. Intravenous propofol (preceded by a modest dose of fentanyl) is an excellent choice for deep sedation (e.g., cardioversion, joint reduction, and other highly painful procedures). Ketamine has been extensively studied by both the IV and IM route for children and is highly effective with a large margin of safety. The same may be said for IV midazolam plus fentanyl in both the adult and pediatric populations.

**Special Considerations for Pediatric Populations**

Performing painful procedures on children in the ED is often distressing for the parent and the provider as well as the child. This often includes obtaining IV access as well as more traditional procedures. In many cases, a calm and reassuring bedside manner, combined with distraction techniques, may be highly successful. Child life practitioners, coloring books, toys, video games, and television may often be helpful.

The advent of ultrafast spiral computed tomography scanners has nearly eliminated the need of sedation for this procedure. For prolonged computed tomography studies or magnetic resonance imaging, deep sedation is generally required in young children. The need and desire for IV access in children should also be considered when planning PSA. Agents such as midazolam may be very effective in infants, but they do not

reliably ensure immobility in young children except at high doses. Methohexital and pentobarbital have demonstrated efficacy for sedating children for these longer imaging procedures. Ketamine has been the most extensively studied and has been shown to be highly effective with a large margin of safety. The use of these drugs may largely be supplanted by propofol use in the future as studies continue to show its efficacy and safety in pediatric PSA.

For mildly painful procedures such as laceration repair or lumbar puncture, topical agents such as cream eutectic mixture of local anesthetics (EMLA); or tetracaine, adrenaline, or cocaine (TAC); or lidocaine, epinephrine, tetracaine (LET) gels in combination with TM or PO midazolam may preclude the need for placement of an IV line.

Brief painful procedures or those requiring deeper sedation may be accomplished with a single IM injection of ketamine. Longer procedures or those requiring IV PSA agents require venous access. This should be considered a mildly painful procedure in itself, and distraction techniques, PO midazolam, and topical agents such as EMLA should be considered if time and the situation permits. Guidelines for patient preparation, personnel requirements, monitoring, drug administration, recovery care, and discharge criteria for children receiving IV PSA are similar to those outlined for adults.

With PSA in children, it is essential that drug dosages be calculated precisely using the child’s current weight and not the parent estimate. Equipment to manage the airway and resuscitation supplies must be size-appropriate, and the physician must be skilled in pediatric airway management and resuscitation.

Chloral hydrate, a pure sedative-hypnotic agent, has been historically popular for sedating children for a wide variety of procedures. It offers no advantage to currently available agents. It has a poor safety record, delayed onset of 45 minutes, prolonged recovery time of hours, and residual sedation of nearly a day. Its use should be discontinued. Likewise, the combination of meperidine (Demerol), promethazine (Phenergan), and chlorpromazine (Thorazine), also known as DPT, is not recommended. It has an unacceptable rate of sedation failure, prolonged sedation times, high risk of respiratory depression, and frequent dystonic reactions.

KEY CONCEPTS

- PSA has become commonplace and should be approached as a complex procedure requiring high-level skills and knowledge.
- Propofol is an excellent agent for deep sedation in the ED.
- Preprocedural fasting is controversial, and guidelines are a benchmark for minimizing risk.
- Pulse oximetry is mandatory during sedation, and end-tidal CO₂ partial pressure should be monitored if deep sedation is the goal.

PERSPECTIVE

Background

Combative patients are among the most difficult patients emergency physicians (EP) encounter. Often brought in against their will, they are agitated, confrontational, nearly impossible to examine, and may physically harm themselves or others. The EP must control the patient and the situation, diagnose and treat reversible causes of violence, and protect the patient and staff from harm.

Epidemiology

Violence is referred to as our nation’s shameful epidemic. Injury is the leading cause of death in persons younger than 44 years, and homicide is the second leading cause of death in persons from age 15 to 24 years. 1 Rates of firearm violence are higher in the United States than in any other industrialized country, 2,3 and the rate of death from firearms is eight times higher in the United States. 4 For each death there are an estimated 19 additional injuries requiring hospitalization. 5 The high lifetime cost of treating gunshot injuries is a public health issue, as a large proportion of the expense is covered by U.S. taxpayers. 6,7

The emergency department (ED) is a volatile environment due to high stress, illness, prolonged waiting times, and frequent lack of communication. The 24-hour open door policy, availability of potential hostages, and widespread accessibility of drugs and weapons compound the potential for violent behavior. Among hospital workers, the majority of assaults occur in the ED, psychiatric ward, waiting rooms, and geriatric units. 8 Up to 50% of human services providers become victims of violence sometime during their careers. 9,10 In a survey of 242 emergency care workers in five Midwestern hospitals, the majority report being verbally threatened, and 51% of physicians and 67% of nurses report being physically assaulted at least once in the past 6 months. 11 Another survey of attending physicians (n = 171) in Michigan EDs reports that 75% experienced a verbal assault and 28% a physical assault in the last 12 months; 82% were occasionally fearful of workplace violence. 12 An ED census of at least 50,000 patients annually or an average waiting time of at least 2 hours is significantly associated with an increased incidence of violence. 13,14 Despite these obvious risks, providers are typically not trained in the identification and management of combative patients.

Patients armed with lethal weapons pose a serious threat to ED staff. The carriage of weapons in the ED population is estimated at approximately 4 to 8%. 15,16 One large urban hospital ED with a metal detector reports confiscating an average of 5.4 weapons a day. 17 At this center, 26.7% of major trauma patients seen in the ED over a 14-year period were initially armed with lethal weapons (84% knives and 16% guns). Unfortunately, predicting weapons carriage in any particular patient is impossible. 18 Therefore, it is prudent to assume that all violent patients are armed until proven otherwise, especially those presenting with major trauma.

Identification of potentially violent patients is difficult, with male gender, prior history of violence, and drug or ethanol abuse the only positive predictors. 19-23 Ethnicity, diagnosis, age, marital status, and education are not reliable identifiers. A study conducted in an outpatient psychiatric setting finds that the incidence of violent behavior occurring after psychiatric evaluation does not vary with the experience of the psychiatrist. 20 Actuarial prediction of patient violence in a 6-month time period using criteria such as age, drug use, and prior history of violence is substantially more accurate than prediction of future violence by evaluating attending psychiatrists. 24 The prediction, prevention, and control of violent outbursts in the ED is difficult. Appreciation of the potential for violence, preparedness, and proper utilization of verbal techniques and physical or chemical restraints assists the patient while preventing injury.

PRINCIPLES OF DISEASE

Pathophysiology

The pathogenesis of violent behavior is conjectural. Potential causes include environmental, historical, interpersonal, biochemical, genetic, hormonal, neurotransmitter, and substance abuse disorders. 25,26 Psychiatric illness is also a risk factor, with schizophrenia (paranoid and nonparanoid), personality disorders, mania, and psychotic depression most frequently associated with violence. 27,28 Delusional schizophrenic patients become violent, believing that others are attempting to harm them. They may also have auditory hallucinations commanding harm to others. Antisocial and borderline personality disorder patients typically do not feel remorse for their violent actions. The patient with acute mania is unpredictably dangerous because of emotional lability, a situation in which pleasantness can quickly turn to aggression. Substance abuse...
disorders are consistently associated with violent behavior in both psychiatric and nonpsychiatric populations. 22,23,30,31

Biologically, the serotonin system controls aggression and inhibition, with diminished serotonergic function possibly disinhibiting aggression against self and others.32-36 Generalized brain dysfunction may predispose patients to violence by disruption of the regulation of aggression, particularly in the prefrontal and temporal cortex. 37-40 Research in cerebral imaging documents both functional and structural impairments in violent criminals and antisocial patients.41,42 Genetic and hormonal influences are also implicated in the neurobiology of aggression. 33,44

MANAGEMENT

Risk Assessment

Evaluation of the combative patient begins with risk assessment and attention to safety measures. Violence often erupts after a period of mounting tension. The astute practitioner may identify verbal and nonverbal cues and subsequently have the opportunity to diffuse the situation. 29,45 In a typical scenario, the patient first becomes angry, then resists authority, and finally becomes confrontational and violent. When physicians have a “gut feeling” that a dangerous situation may be developing, they should take appropriate precautions. 46 Violent behavior may also erupt without warning, especially in patients with an organic brain syndrome (OBS), so clinicians should not feel overly confident in their ability to sense impending danger.

An obviously angry ED patient should always be considered potentially violent. Provocative behavior, an angry demeanor, pounding, loud or pressured speech, tense posture, gripping arm rails intensely, frequently changing body position, pounding walls or throwing things, and clenched fists are all symptoms and signs of impending violence. The patient should be removed from contact with other belligerent accomplices, as well as from other provocative patients, to prevent escalation. A quiet area with a window or direct observation is optimal. Since increased waiting times correlate positively with violent behavior, 8,13,14 consider evaluating the potentially violent patient expeditiously to prevent escalation of aggression. Often, the perception of preferential treatment will defuse patient anger.

All patients should be screened for weapons before the interview. The use of metal detection is ideal before ED entry. The practice of undressing patients and placing them in a gown is useful both as a nonconfrontational search for weapons and for easy identification in the event of patient escape from the ED. Although screening and searching patients for weapons may appear to be a violation of privacy, routine disarming of all ED patients results in an increased feeling of safety for both patients and staff. 16,47

The ideal setting for the patient interview should emphasize privacy but not isolation. 27,46 Some EDs have seclusion rooms specifically designed for interviewing potentially dangerous patients. 46 Security should be nearby and the door left open to facilitate both intervention and escape. The patient and interviewer may be seated roughly equidistant from the door, or the interviewer may sit between the patient and the door. Blocking the door, however, poses a risk of harm to the clinician if the patient feels the urge to escape. Ideally two exits should be available and doors should swing outward. The clinician should have unrestricted access to the door and never sit behind a desk. The room should not contain heavy or potentially dangerous objects that may be thrown. There must be a mechanism for alerting others of danger, such as a panic button or a code word or phrase that summons security (e.g., “I need Dr. Armstrong in here”). For personal protection, earrings, necklaces, and neckties should be removed. Personal accessories that may be used against the EP, such as a stethoscope or scissors should be removed. The physician should be aware of any objects within the room or on the patient’s body, such as pens, watches, or belts that may be used as weapons. 45,46,49,50

Verbal Management Techniques

The patient should be made as comfortable as possible, and the interviewer should adopt an honest and straightforward manner. In some cases, an agitated patient may be aware of their impulse control problem and welcome limit-setting behavior by the clinician (e.g., “I can help you with your problem, but I cannot allow you to continue threatening me or the ED staff.”). The interviewer should act as an advocate for the patient. Offering a soft chair or something to eat or drink (not a hot liquid, which may be used as a weapon) may help to establish trust. A significant percentage of patients relax at this point, because offering food or drink appeals to their most basic human needs and builds trust. The interviewer should adopt a nonconfrontational demeanor and be an attentive and receptive listener without conveying weakness or vulnerability. The interviewer should respond verbally in a calm and soothing tone of voice. It is also important to stand at least an arm’s length away and avoid prolonged direct eye contact, approaching the patient from behind, or sudden movements.46

A key mistake when interviewing a potentially violent patient is failing to address the issue of violence directly. 20,45,51 The patient should be asked relevant questions regarding suicidal or homicidal ideations or plans, possession of weapons, history of violent behavior, and current use of intoxicants. Acknowledgment of the obvious (e.g., “You look angry.”) may help the patient to begin sharing emotions. If the patient becomes more agitated, it is important to speak in a conciliatory manner and offer supportive statements, such as “You obviously have a lot of will power and are good at controlling yourself,” to help defuse the situation. If this is not successful, a respectful offer of medication or restraints to the patient if another health care provider is close by may prevent further escalation.

Counterproductive approaches to the combative patient include argumentation, machismo, or condescension. These inappropriate strategies challenge patients to “prove themselves.” An open threat to call security personnel also invites aggression. The clinician must be aware of her or his own reactions to the patient and avoid countertransference of anger. The deception of a patient (e.g., “I am sure you will be out of here in no time.”) only invites violent consequences once the lie is uncovered. The unsuspecting nurse or colleague who follows the interviewer may be victimized.

It is especially important not to deny or downplay threatening behavior. If verbal techniques are unsuccessful, the physician should leave the room and summon help.

Physical Restraints

Physical restraint should be considered when, despite a professional and proper approach to the combative patient, verbal techniques are unsuccessful. The use of restraints can be humane and effective in facilitating diagnosis and treatment of the patient, while preventing injury to the patient or medical staff. 49,52,54 The liability one incurs for restraining a patient
against his will is negligible compared with the potential liability for allowing a patient to lose control and cause physical harm.\(^{46}\) Indications for emergency seclusion and restraint include the prevention of imminent harm to the patient, to others, and to the environment or as part of an ongoing behavior treatment program.\(^ {46,55}\) Seclusion or restraint may be contraindicated due to the patient’s clinical or medical condition. Seclusion should not be used in an unstable patient who requires close monitoring and should be avoided when the patient is suicidal, self-abusive, self-mutilating, or has had an intentional ingestion of drugs or poisons.\(^ {79,49,56}\) Restraints should not be applied for convenience or as a punitive response for disruptive behavior. If available, a colleague should document agreement with the application of restraints, mentioning the specific indications (e.g., “I restrained Mr. Smith because he told me he was going to beat me up and then took a swing at me” is preferable to “I restrained Mr. Smith because he was violent”).

The application of restraints should be systematic, and an ED protocol should be in place. This protocol begins when the examiner leaves the room after verbal techniques are unsuccessful. It may be helpful to consider the application of restraints as a procedure analogous to running an advanced cardiac life support code.\(^ {49}\) The restraint team ideally consists of at least five people, including a team leader. The leader, whether a physician, nurse, or security officer, will be the only person giving orders and should be the person with most experience in implementing restraints. Before entering the room, the leader outlines the restraint protocol and warns of anticipated danger (e.g., the presence of objects that may be used as weapons). All team members should remove personal objects that the patient could use against them. If the patient is female, at least one member of the restraint team should be female to potentially mitigate allegations of sexual assault.

The team enters the room in force and displays a professional, rather than threatening, attitude. Many violent individuals calm down at this point, as a large show of force protects their ego (e.g., “I would have fought back but there were too many against me.”). The leader speaks to the patient in a calm and organized manner, explaining why restraints are needed and what the course of events will be (e.g., “You require a medical and psychiatric examination as well as treatment.”). The patient is instructed to cooperate and lie down to have restraints applied. Some patients are relieved at the protection to self and others afforded by restraints when they feel themselves losing control. Even if the patient suddenly appears less dangerous, however, once the decision to restrain is made, do not negotiate.

If physical force becomes necessary, one team member restrains a preassigned extremity by controlling the major joint (knee or elbow). The team leader controls the head. If the patient is armed, two mattresses can be used to charge and immobilize or sandwich the patient. Restraints are applied securely to each extremity and tied to the solid frame of the bed (not side rails, as later repositioning of side rails also repositions the patient’s extremity). Leather is the optimal type of restraint because it is physically stronger material and less constricting than typical soft restraints. For this reason, gauze should not be used. Soft restraints may help restrict extremity use in the semicooperative patient but are likely to be less effective in the truly violent patient who is continuing to struggle and attempt escape. If chest restraints are used, it is vital that adequate chest expansion for ventilation is ensured. The application of a soft Philadelphia collar to the patient’s neck minimizes head banging and biting. Whenever possible, the treating physician should not actively participate in restraint application to preserve the physician-patient relationship. The restraining of patients on their sides helps prevent aspiration, although restraint supine with the head elevated is more comfortable and allows a more thorough medical examination while providing some protection against aspiration.\(^ {79,57}\) Once the patient is immobilized, announcing “the crisis is over” will have a calming effect on the restraint team and the patient.

After restraints are successfully applied, the patient should be monitored frequently and positions changed to prevent neurovascular sequelae such as circulatory obstruction, paresthesias, and rhabdomyolysis associated with continued combative behavior. A standardized form should be developed for physically restrained patients. Documentation should include the specific indication for restraint and, ideally, colleagues’ agreement that restraints are necessary.

Sudden, unexpected deaths are reported in restrained patients.\(^ {58-64}\) Although healthy volunteers, when restrained and undergoing physical exertion, do not appear to experience clinically significant positional asphyxia,\(^ {63-65}\) the combative ED patient often suffers from other conditions that may predispose to increased morbidity. Patients who are cocaine- or stimulant-intoxicated or restrained in the prone position appear to be uniquely at risk for adverse outcomes.\(^ {58-61}\) Increased sympathetic tone and altered pain sensation are postulated to allow exertion beyond normal physiologic limits in these patients. Sympathetic induced vasoconstriction may impede clearance of metabolic waste products. Alteration of respiratory mechanics in an acidic patient resulting from restraint position could be a contributing factor by impairing respiratory compensation. As a general guideline, the prone restraint position should be avoided when possible and chemical sedation used when a patient continues to struggle against physical restraints.

The Joint Commission on Accreditation of Health Care Organizations (JCAHO) has guidelines governing the use of restraint and seclusion for behavioral health patients. Educational materials regarding seclusion and restraint are available at http://www.jointcommission.org/. Several essential elements must be provided in a restraint situation including:

1. Hospital policies and procedures guide appropriate and safe use of restraint.
2. The implementation of restraint or seclusion is limited to emergencies where imminent risk of harm exists to the patient or others.
3. Staff is trained and competent to apply restraint safely.
4. Staff is trained to minimize the use of restraint.
5. Patients in restraint are regularly evaluated and monitored.
6. Orders for restraint use are provided by licensed practitioners and are time-limited.
7. Medical records document that the use of restraint or seclusion are consistent with organizational policy.

### Chemical Restraints

Chemical restraint may be necessary to control an agitated patient and may be used in conjunction with physical restraint. The ideal pharmacologic agent should be effective with multiple routes of administration, nonaddictive, immune to tolerance, and have a low side effect profile. Antipsychotic medications, also called neuroleptics, are useful for rapid tranquilization due to their high therapeutic index, lack of tolerance to the desired effects, and lack of addictive potential. Classic antipsychotics block dopaminergic receptors and also have variable effects on cholinergic, adrenergic, histaminic, and serotonergic receptors. Antipsychotics can be divided into low potency (e.g., chlorpromazine, mesoridazine, thioridazine), midrange potency (e.g., loxapine, molindone), and high
potency (e.g., haloperidol, fluphenazine, thiothixene, trifluoperazine). The incidence of sedation, hypotension, and seizures is higher in the low-potency group, and the incidence of extrapyramidal symptoms (EPS) is greatest in the high-potency group.

Until recently, haloperidol (Haldol) has been recommended as the drug of choice to sedate violent patients as it was the only neuroleptic agent with an intramuscular (IM) or intravenous (IV) route of administration. Haloperidol is generally administered at dosages of 2.5 to 10 mg IM at 30- to 60-minute intervals, with half doses used in the elderly.

After IM injection, effects are typically seen in 10 to 30 minutes, with most patients requiring less than three doses to achieve the desired effect. Although no ceiling dose has been established, it has been recommended that patients not receive more than six doses in 24 hours. Using the lowest effective dose minimizes the risk of side effects.

Of note, haloperidol is not approved for IV administration by the U.S. Food and Drug Administration (FDA); however, it has been used safely and effectively via this route with such widespread acceptance that FDA approval will most likely be deferred indefinitely.

Droperidol (Inaparine), an analogue of haloperidol, has also been used with success at doses of 5 to 20 mg IM to control an agitated patient. Compared with haloperidol, droperidol has a shorter duration of effect, a lesser incidence of EPS, and a greater incidence of sedation and orthostatic hypotension.

The use of droperidol has been limited since it was given a black box warning in 2001 by the FDA for cases of QT prolongation and torsades de pointes.

The most common side effects of haloperidol and droperidol include sedation, orthostatic hypotension, and EPS. Extrapyramidal symptoms are not dose-related, can occur after one dose, and may occur up to several days after administration. After acute administration, patients may develop akathisia (extreme restlessness) or acute dystonia, which may manifest as involuntary turning or twisting movements seen in the neck (torticollis), back, and eyes (oculogyric crisis). Rarely, the mouth and tongue can be affected, compromising the airway. The treatment for each of these symptoms is benztropine (Cogentin), 1 to 2 mg, or diphenhydramine (Benadryl), 25 to 50 mg, either IM or IV. Relief generally occurs within minutes. Haloperidol and droperidol have negligible anticholinergic properties and are often coadministered with anticholinergic agents (benztropine or diphenhydramine) in order to attenuate dystonia.

Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction that leads to autonomic instability. Symptoms include hyperthermia, hypertension, and lead-pipe rigidity of extremities. This reaction occurs in an estimated 0.2% of patients receiving antipsychotic medications. Clinicians should be familiar with this syndrome when administering antipsychotic medications. If NMS develops, supportive care should be administered and further neuroleptic medications withheld.

Some neuroleptic medications (especially phenothiazines such as chlorpromazine) may lower seizure threshold; therefore the use of neuroleptics in sympathomimetic-intoxicated patients has been controversial. In clinical practice, seizure activity occurring after haloperidol or droperidol administration appears to be a rare event. In addition, haloperidol has been found in an animal model to prevent seizures in cocaine and amphetamine intoxication.

Conduction disturbances, specifically prolongation of the QT interval and in some cases torsades de pointes, have been reported in patients sedated with haloperidol. A 2007 FDA alert recommends electrocardiographic (ECG) monitoring in patients receiving IV haloperidol due to the possible risk of QT prolongation and torsades de pointes. Rapid tranquilization with newer medications is considered safe and effective in the treatment of psychotic and potentially assaultive patients. Atypical antipsychotic agents (e.g., risperidone, olanzapine, quetiapine, ziprasidone) have largely replaced typical antipsychotics in the first-line treatment of schizophrenia due to increased efficacy on both positive and negative symptoms and a significantly decreased incidence of movement disorders compared with typical antipsychotic agents such as haloperidol.

The use of atypical antipsychotic agents to treat the acutely agitated or psychotic patient in the ED setting has been historically limited by slow titration regimens and the lack of an IM route of administration. Intramuscular formulations for some of the atypical antipsychotics have since been developed and appear to offer promising additions to our current pharmacologic armamentarium when treating the combative patient acutely. They also allow for a smooth transition to oral dosing in those patients requiring ongoing antipsychotic therapy.

In several randomized, double-blind, and placebo-controlled studies, atypical antipsychotics have proven useful. Olanzapine at 2.5 mg and 5.0 mg IM is equivalent to lorazepam 1 mg IM in controlling acute agitation in elderly patients with Alzheimer’s or vascular dementia. Olanzapine 10 mg IM is superior to lorazepam 2 mg IM in controlling acute agitation in patients with bipolar mania. Olanzapine doses of 5, 7.5, and 10 mg IM are more rapidly effective than haloperidol 7.5 mg IM in controlling acute agitation in patients with schizophrenia. The most common side effect noted is mild hypotension. QTc prolongation is comparable with that from placebo, and olanzapine is significantly less likely than haloperidol to produce dystonia and movement disorders.

In addition, olanzapine IM produces distinct calming rather than nonspecific sedation. Olanzapine, however, has significant anticholinergic properties and can potentially exacerbate an anticholinergic delirium. A Cochrane Collaboration review of olanzapine IM concludes that it may be valuable in managing acute agitation, but more studies are needed. Olanzapine IM is FDA approved for the treatment of acute agitation associated with bipolar I mania and schizophrenia. Recommended dosing for olanzapine IM is 2.5 to 10 mg initially, followed by up to two more doses 2 to 4 hours apart, for a total maximum dose of 30 mg.

Intramuscular ziprasidone at doses of 10 and 20 mg is effective in reducing acute agitation in patients with underlying psychotic disorders. A randomized, open-label study comparing ziprasidone and haloperidol for the treatment of acute psychosis finds that ziprasidone (10 mg IM followed by 5–20 mg q4–6 hr) is superior to haloperidol (2.5–10 mg IM and q4–6 hr) in reducing agitation and improving scores on psychiatric assessments as measured every 24 hours for 3 days. The most common side effect is dose-related sedation. An observational study of ziprasidone IM in 110 adult patients with acute agitation (35% substance-related) seen in a psychiatric ED reports rapid efficacy and decreased total restraint time compared with historical controls. A randomized, double-blind trial comparing droperidol at 5 mg IM, ziprasidone at 20 mg IM, and midazolam at 5 mg IM to treat acute undifferentiated agitation in the ED (primarily intoxication related) finds that adequate sedation is delayed with ziprasidone relative to the other agents, rescue medication is required more frequently with midazolam, and the most common adverse events are mild respiratory depression and akathisia.

Ziprasidone has more effect on the QTc interval than olanzapine, haloperidol, or risperidone. In a regulatory study, ECGs performed at the times of peak plasma concentrations of various antipsychotics show that ziprasidone averaged a 16 ms increase in the QTc interval from baseline.
Special Populations

Section Nine

Aripiprazole 9.75 mg IM in several double-blind, randomized, placebo-controlled studies is equivalent to haloperidol IM (6.5 mg or 7.5 mg) in the treatment of acute agitation in patients with schizophrenia, with a lower incidence of EPS.110-112 Aripiprazole 9.75 mg IM and 15 mg IM in another study is equivalent to lorazepam 2 mg IM in the treatment of acute agitation in patients with bipolar disorder.113 Aripiprazole IM is FDA approved for the treatment of acute agitation associated with schizophrenia or bipolar disorder. Recommended doses are 5.25 to 15 mg IM, repeated every 2 hours, to a maximum of 30 mg.114

Although these newer intramuscular atypical antipsychotic agents appear to be effective in the chemical restraint of specific populations of agitated patients, their use in the ED treatment of the combative patient with undifferentiated agitation is not fully defined at this point. The atypical antipsychotics may evolve as first-line treatment of acute agitation in psychiatric patients.53,69,115

Benzodiazepines can also be used for rapid tranquilization of an agitated patient, with lorazepam proving superior to other benzodiazepines due to rapidity of action, effectiveness, short half-life, lack of active metabolites, and IM or IV route of administration.52,69,116 Benzodiazepines are especially useful in the patient who is agitated due to intoxication or withdrawal while still maintaining efficacy in acute psychosis.23 Recommended doses of lorazepam start with 2- to 4-mg increments IV, IM, or orally (PO) and are titrated upward as needed, up to 120 mg in 24 hours.96 Midazolam, a shorter acting benzodiazepine, has been compared with lorazepam and haloperidol in the severely agitated patient.117 Midazolam 5 mg IM was compared with lorazepam 2 mg IM or haloperidol 5 mg IM in a randomized, prospective, double-blind trial and has a more rapid onset of action but also a shorter duration of activity than either lorazepam or haloperidol. The most common side effects of benzodiazepines are sedation, confusion, ataxia, and nausea. Respiratory depression is the most significant risk when benzodiazepines are used in a patient who is already under the influence of a potential respiratory depressant such as ethanol.

Antipsychotics and benzodiazepines can be used alone or in combination. The combination of lorazepam with haloperidol has been studied prospectively and was superior to either drug alone in a randomized, double-blind, multicenter trial.116 ED patients with undifferentiated agitation were treated with lorazepam 2 mg, haloperidol 5 mg, or both in combination. Doses were repeated as needed at hourly intervals, up to six times. Patients were reevaluated hourly for efficacy, vital signs, and presence of side effects for a total of 12 hours. Patients receiving combination therapy improved significantly more in the first 3 hours than those receiving either drug alone, and more patients experienced EPS in the haloperidol-alone group than in the combination group, possibly because of a greater number of doses needed. Based on these findings, combination therapy has been endorsed for rapid tranquilization of the acutely agitated patient for optimal effect and minimal side effects. The use of 5 mg of haloperidol IV or IM with 2 mg of lorazepam IV or IM, repeated every 30 minutes to effect, is often recommended to treat the combative patient with undifferentiated agitation and without contraindications to these medications.52,68,88,115,118,119 Half doses should be used in the elderly. These medications are compatible within the same syringe for up to 16 hours.120

Rapid tranquilization calms patients so they can cooperate in their evaluation and treatment and avoid harming themselves or others. Although obscuring the mental status with medication can confuse the clinical diagnosis, these considerations must be weighed against placing the patient and medical staff at increased risk by withholding effective medications. In addition, physical restraint alone, especially in a struggling patient, may increase the risks for patient morbidity and mortality.

Assault

Unfortunately, physical assault may occur despite appropriate precautions and interventions. If assaulted, immediately summon help. Maintain a sideward posture, keeping the arms ready for self-protection. If faced with a punch or a kick, deflect with an arm or a leg. If choking is attempted, tuck the chin in to protect the airway and carotids. If bitten, do not pull away but rather push toward the mouth and hold the nares shut to entice opening of the mouth. If threatened with a weapon, try to appear calm and comply with demands.46 Adopt a nontreating posture and avoid sudden movements. Do not attempt to reach for the weapon. Avoid argument, despair, or whining. Attempt to establish a human connection with the hostage taker.27,121 Offering to administer to other ill or injured hostages allows a hostage to appear less expendable. Do not bargain or make promises, and do not lie, as the consequences could be disastrous. Reassure the hostage taker that someone authorized to hear the complaint or demand should arrive promptly.123 If a weapon is put down, do not reach for it but rather attempt to verbally resolve the crisis while awaiting the arrival of security personnel. Legal authorities can be called on to provide a professional hostage negotiator if one is needed.

Each hospital should have a plan of action for cases of extreme violence. The plan should include prevention and safety measures, a means for rapid notification of security and police personnel, evacuation plans, medical treatment, and crisis intervention.46,121,122 A novel approach uses a violence management team trained in the preceding techniques to provide a mechanism for dealing with aggressive patients and protecting the staff.123

CLINICAL FEATURES

History and Physical Examination

Once combative patients are controlled, they need to be evaluated for organic causes of their agitated behavior. Separating functional from organic disease is a challenging task complicated by the fact that many patients with psychiatric disorders suffer from organic medical disorders that may worsen their symptoms. Patients who exhibit violent behavior that is caused or exacerbated by an organic problem may rapidly deteriorate if the medical issues are not addressed in a timely fashion. A focused history and physical examination assists the physician in differentiating functional from organic illness and facilitates a cost-effective and timely diagnosis.
Several historical features distinguish functional (psychiatric) from organic (medical) illness. Patients older than 40 years who have a new onset of psychiatric symptoms are more likely to have an organic cause.\textsuperscript{124,125} Also, elders are at higher risk for organic delirium due to medical illness or adverse reactions to medications. Patients with a history of drug or ethanol abuse may exhibit violent behavior as a manifestation of an intoxication or withdrawal syndrome. The acute onset of agitated behavior, as well as behavior that waxes and wanes over time, suggests an organic origin. Most psychiatric patients are alert and oriented and have a past psychiatric history. Table 188-1 lists clues for distinguishing functional from organic causes of violent behavior.

The history of present illness should include psychiatric, medical, family, and social information, including suicidal ideation, medication use, and any recent changes to prescribed medications. Often family and friends can provide valuable details, as the agitated patient may not be a reliable source of information. When available, they should be interviewed independently from the patient. Medical records may detail medical and psychiatric history as well as prior history of violence. Drug and ethanol use is an important part of the history, as substance abuse is highly correlated with violent behavior.

The patient should be asked for permission for the physician to perform a thorough physical examination to search for an organic cause of violent behavior and uncover any resulting injury. Patient restraint may be necessary to accomplish even the most rudimentary physical examination. The importance of obtaining routine vital signs including temperature and performing a thorough mental status and neurologic examination cannot be overemphasized. Patients with persistently abnormal vital signs, a clouding of consciousness, or focal neurologic findings are more likely to suffer from organic disease and require further diagnostic evaluation. A careful physical examination should focus on the patient’s general appearance (e.g., hygiene, nourishment, tremors) and vital signs, evidence of trauma or needle tracks, characteristic odors, neurologic and mental status examination, and signs of a possible toxidrome (Table 188-2).\textsuperscript{126}

### Diagnostic Strategies

Diagnostic studies should be guided by the information obtained from the history and physical examination. Although some authors advocate a standardized panel of laboratory and radiographic studies for patients with psychiatric symptoms, most recommend tailoring diagnostic studies based on clinical findings.\textsuperscript{118,124,127-130}

A rapid blood glucose determination and pulse oximetry should be obtained on all combative patients. Patients younger than 40 years of age with a prior psychiatric history, a normal physical exam including vital signs, a calm demeanor, normal orientation, and no physical complaints likely require no further diagnostic testing.\textsuperscript{129} Additional studies that may be useful in selected patients include serum electrolytes, blood and urine toxicology screening, serum ethanol, thyroid function panel, cranial imaging, and electroencephalography (EEG).\textsuperscript{25,28,46,124} A lumbar puncture may be performed if a CNS infection is suggested. Specific medication levels may be determined when toxic levels would affect therapy. An ECG may be useful in elders and in the setting of a suggested intentional ingestion. Patients who may have intentionally ingested a toxic substance should also have an acetaminophen level measurement, as this potentially fatal ingestion may be difficult to diagnose clinically and has an effective treatment.

An additional consideration in the diagnostic workup must be the concern of the psychiatrist who will ultimately evaluate the patient. Although serum ethanol and toxicology screening may not significantly influence a patient’s treatment, the psychiatrist may use them to assess the degree to which ethanol

or drug use contributes to the patient’s behavioral issues. Ideally, an agreement on a diagnostic strategy should be reached between the psychiatrist and EP prior to referral. Unnecessary diagnostic testing prolongs ED length of stay and delays definitive psychiatric care.

### DIFFERENTIAL CONSIDERATIONS

Violent behavior often occurs in association with head trauma, hypoxia, hypoglycemia, electrolyte imbalance, infections (particularly herpes encephalitis), drug intoxication or withdrawal or adverse reaction, and metabolic and endocrine derangements. Uncommon organic causes include seizures (e.g., temporal lobe, limbic); tumors, particularly those in the limbic system; limbic encephalitis; multiple sclerosis; porphyria; Wilson’s disease; Huntington’s disease; sleep disorders; hyperparathyroidism; and vitamin and mineral deficiencies (e.g., folate, vitamin B12, niacin, and vitamin B6). In the ED setting, drug and ethanol intoxication or withdrawal are the most common diagnoses in combative patients. The mnemonic FIND ME (functional, infectious, neurologic, drugs, metabolic, endocrine) helps to organize a diagnostic search for the cause of violence (Box 188-1).

### Medical Clearance

The EP often provides “medical clearance” for the psychiatric or combative patient. It must be recognized that “medical clearance” is a misnomer and that on completion of the ED evaluation the patient is not “cleared” of all possible medical conditions. In addition, there is no standard process of providing what may be more accurately termed a “focused medical assessment.”

The incidence of organic disease in patients presenting with psychiatric complaints ranges from 24 to 80%. The more relevant issue for the EP is to detect medical problems that are causing or contributing to the patient’s violent behavior. Misattribution of aberrant organic behavior in a patient with known psychiatric pathology is a common cause of litigation. The EP should recognize that most psychiatrists rely on their medical assessment of the patient. Low risk patients with functional illness can be rapidly referred for psychiatric evaluation once they are calm and able to cooperate with a therapeutic psychiatric interview. Patients who are identified by a focused history and physical examination as being at higher risk for an acute organic illness require further diagnostic studies.

Once the medical screening evaluation is completed the findings should be communicated to the consulting psychiatrist. The medical record should reflect that the evaluation showed no evidence that an acute medical condition caused or contributed to the patient’s behavior. If the cause of the patient’s violent behavior is drug or ethanol intoxication, the patient should be observed until he has reached the point where a therapeutic intervention can be conducted by the psychiatrist. Alternatively, the patient may be transported to a facility where observation can occur until the effects of the intoxicants have abated. Rather than pronouncing the patient “medically clear,” the EP should clearly document his findings and recommendations to the consulting psychiatrist.

### Preparing the Emergency Department to Prevent Violence

The risk of violence in the ED should be minimized in a cost-effective manner without creating a hostile or negative environment. The prevention of violence is best accomplished by developing a system that includes ongoing staff education, adequate personnel, and a well-designed physical structure. The personnel and features used in an institution’s violence prevention program must be selected based on the assessment of risk in each facility.
Security Personnel

A well-trained and responsive security force is a key element of any hospital security system. Such personnel are expensive, and their expertise is often sacrificed quickly during budget curtailments, so decisions regarding the type and number of guards are often made on an economic basis. The use of guns by hospital security personnel is controversial, as is allowing other armed law enforcement officers into the ED. Other devices such as the Taser, stun gun, and mace are suggested as less lethal alternatives to guns.

Patient Searches

Searching patients for weapons as they enter the ED is permissible when performed in a nondiscriminatory manner.121 Warning signs should be prominently displayed, perhaps reading: “For the safety of patients and staff, individuals entering the ED may be screened for weapons.” Almost all patients and families will cooperate with searches and may actually feel safer as a result.47 Clear written policies regarding searches and disposal of contraband must be distributed to the staff and closely followed.

Alarm Systems

The goal of any alarm system is to obtain rapid appropriate response with a minimum of false alarms. A tiered alarm system is usually best. Panic buttons in each room activate a central buzzer in the department. Several designated ED personnel respond initially and then judge the level of response needed. Every ED should have at least one telephone with a direct line to police or security in case additional personnel are deemed necessary. A verbal code (e.g., “Dr. Armstrong to Room 9”) is also a useful adjunct.36

Limited Access to the Emergency Department

Controlling flow into the ED can be an effective method of preventing violent acts. High risk departments should limit access to one or two entrances, especially during the evening hours. Bulletproof glass barriers and buzzer access systems are useful as well.

Use of a Designated Room

ACEP recommends that most EDs contain at least one secure examination room with shatterproof ceiling lights, a solid ceiling, heavy indestructible chairs, a well-secured restraint bed, two doors that can be locked from the outside, and an emergency distress button that can be activated unobtrusively.121 If desired, this room can be set up for video monitoring by security or ED staff.

One large urban county hospital with a high incidence of violent behavior in the ED is equipped with a large security force, metal detectors, a bulletproof Plexiglas triage area, a keypad security entry, controlled entryway into the ED, and metal bars to prohibit cars from driving into the department.17 The hospital reports no incident of weapons-related violence or injury in the ED since these measures have been implemented.

Prevention

The concepts of primary, secondary, and tertiary prevention of violence can be applied to the ED environment.13 Primary prevention refers to trying to control those factors that encourage the development of frustration and aggression. Long waiting times are associated with development of violent behavior. Attempts to shorten waiting times and make the waiting room environment as pleasant as possible may diminish previolent aggression. The presence of surveillance cameras and a visible security force also act as deterrents.

Secondary prevention of violence involves response to previolent agitation and aggression. Successful intervention involves the recognition of risk and implementation of de-escalation techniques. Staff should be trained to recognize previolent individuals who should be seen in a timely manner. Often the aura of preferential treatment defuses the situation.123 Training of staff in techniques for managing violence leads to increased staff confidence and comfort while decreasing the rate of aggressive incidents.137,138

Tertiary prevention refers to limitation of the actual act of violence itself once it has occurred. Physical and chemical restraints are used, and security and police intervention are often needed. Protocols for dealing with the violent patient are important to minimize risks to the patient and staff. Enhanced security measures may be indicated in an ED with substantial risk for violence.

Violence is increasingly a major public health issue, with increased focus on improving surveillance and universal preventive measures to target large populations.139,141 Physicians are increasingly aware of their role in reducing violence. Firearm regulations, hospital security mandates, and legislation for education of practitioners in the prevention and treatment of violence represent current controversies in which EPs should have a voice. A proposed agenda for violence prevention for emergency medicine includes improvements in medical education, research, and clinical practice, as well as involvement with public education and advocacy.142

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Certain patients consistently arouse negative reactions in health care providers. These negative reactions may be initiated by a patient’s appearance, apparent attitude, interactive style, or presenting complaint. Difficult patients can rapidly disrupt the harmony and efficiency of an emergency department (ED). Such patients have been referred to with a number of pejorative terms, such as gomer, crock, and other even less complimentary slang terms of disdain. They may receive suboptimal medical care, impede patient flow, and adversely influence the quality of care given to other patients, thus posing a medicolegal risk. Moreover, recurrent exposure to such patients, in the absence of a well-thought-out approach to dealing with them, may lead to escalating frustration for staff, promote unprofessional behaviors, and contribute to eventual burnout.

Historically, the medical literature has largely ignored the possibility of physicians harboring negative feelings toward any type of patient. Anger, hatred, and frustration are traditionally considered feelings that physicians should disown in favor of humor, compassion, and integrity. Although the latter are admirable attributes, to deny the presence of negative reactions is unrealistic. Physicians are as human as the patients they serve. Not until Freud coined the term countertransference were the negative reactions that patients can arouse in physicians actually recognized for their potential effect on care and used as diagnostic tools.

Good interpersonal skills are essential to the maintenance of the patient-physician relationship. Although some clinicians have more natural abilities in this area than others, the myth that these skills are intuitive and cannot be taught is erroneous. Teaching communication and relationship-building skills is now a priority of most medical schools and many primary care specialties. The need for guidelines for teaching and evaluating interpersonal skills within emergency medicine residency programs has only recently been addressed. The Accreditation Council for Graduate Medical Education (ACGME) has identified professionalism and interpersonal communication skills as two of the six core competencies required in the curriculum of all U.S. residency programs, including emergency medicine, prompting greater interest in research and education in these areas. Although it remains a challenge to measure the effectiveness of these initiatives, innovative curricula on professionalism and communication are being implemented in emergency medicine residencies.

Difficult patients are often referred to as “problem patients,” “disruptive medical patients,” “unwanted patients,” and, less diplomatically, “hateful patients.” Patients with personality disorders are commonly included in this group because of their rigid, maladaptive personality traits. Difficult patients, however, do not necessarily have personality disorders and may fall into one of several other familiar patient categories (e.g., drug seekers, hostile patients, malingerers, and ED repeaters).

There is no universally agreed on definition of the difficult patient. We define the difficult patient as one who interferes with the physician’s ability to establish a normal patient-physician relationship. This impaired patient-physician relationship is often, but not necessarily, associated with negative feelings toward the patient.

An understanding of the difficult patient-physician relationship is hampered by a tendency to view it as a consequence of some inherent problem with the patient. Physician characteristics and the ED environment also play a role.

Physician Factors

Impaired communication is a common problem in all forms of interpersonal relations and is often exaggerated in the medical setting. Patient satisfaction is highly correlated with patients’ beliefs that clinicians listen to them and understand their requests, coupled with the perceived professionalism of the physician. Despite this, physicians continue to focus on their own medical agenda, which may differ from patients’ concerns. When confronted with patients who have difficult social situations, physicians exacerbate the problem when they refuse to deviate from their own rigid medical model.

Physicians often have preconceived notions regarding how patients should behave when they are ill and tend to rapidly categorize them as either the acceptable “truly sick” patient type or the “burdensome, difficult” patient type. Patients placed within the former category are excused for their symptoms, but patients in the latter category are not. Patients may also be judged as difficult when cultural differences or language barriers interfere with the develop-
ment of a mutual understanding between patient and physician.\textsuperscript{13}

Physician failure to provide sufficient and interpretable information to patients about their diagnosis, treatment, and follow-up evaluation is another area of common communication breakdown. Studies show that in 20 minutes of patient-physician interaction, only 1 minute is reserved for educating patients about the illness.\textsuperscript{15} Personal biases and prejudices also affect patient treatment.\textsuperscript{11,16} The rapid formulation of an opinion based solely on appearance is a skill that physicians rely on to quickly form a “gestalt” about a patient. This is an essential skill for an emergency physician. To assume that such preconceived notions are influential only in a positive way, however, is unrealistic.

**Emergency Department Factors**

The ED is an environment plagued with distractions and frequent interruptions, rarely approaching the comforting atmosphere that many patients expect and deserve.\textsuperscript{17} A sense of urgency and strict time constraints are often present. Patient assessments are sometimes conducted in suboptimal environments, such as hallways. The physician interaction is often perceived to be brief and punctuated by interruptions, which may imply to the patient that the physician does not care or that their evaluation is incomplete.\textsuperscript{17-19} Patients may enter the encounter frustrated because of a lack of choice regarding their physicians or facilities and upset because of long waiting times, and physicians may enter the encounter biased by nursing comments or stressed by the prospect of losing control of the department while trying to deal with these particularly challenging patients.\textsuperscript{13}

**The Cycle of Impaired Patient-Physician Relationships**

Difficult patients are deemed to make unreasonable demands on physicians (Fig. 189-1). Physicians react with negative feelings and may direct negative actions toward the patient. Patients are sensitive to these negative reactions, feel threatened with abandonment, and attempt to sustain the relationship by escalating symptoms. Physicians experience greater frustration at the maladaptive behavior of the patients, and so the cycle is perpetuated.

The consequences of this impaired relationship for the patient include failure to identify the real problems, missing medical diagnoses, “another poor experience” with the medical establishment, and premature or inappropriate discharge.\textsuperscript{1} The negative effect on the staff is manifested by frustration, a sense of failure and defeat, fear of litigation, and the development of unconstructive stereotypes and unrecognized prejudices, all of which may contribute to eventual professional burnout.

**STRATEGIES FOR TREATING THE DIFFICULT PATIENT**

This section discusses the treatment of difficult patients from three approaches: general strategies, dealing with negative reactions, and crisis intervention.

**General Strategies**

Box 189-1 lists several general strategies that are helpful in dealing with difficult patients.

![Figure 189-1. Cycle of the impaired patient-physician relationship.](image-url)
General Strategies for Dealing with Difficult Patients

- Be supportive.
- Structure the interview.
- Set limits.
- Point out impasses.
- Share your reactions.
- Redirect the interview.
- Take time out.
- Use teamwork.
- Understand the patient’s agenda.

Be Supportive

Being supportive is not always the natural response to difficult patients because of the negative feelings they arouse in the physician. Nevertheless, initiating the interaction with a clear and explicit demonstration of concern and empathy may be the single most powerful tool at one’s disposal. Some physicians are concerned that seeming to be “soft” with a demanding or entitled patient may exacerbate the situation. To the contrary, expressing a respectful and empathetic concern for their problem effectively disarms many patients who are preparing for a long and arduous battle to be taken seriously. The possible news that there is no immediate solution available is more willingly received by patients who are convinced that they have been heard and believe the physician’s desire to help is sincere.

Connecting emotionally with the patient can take time. Initially addressing a smaller concern in a caring and respectful manner can build trust and create greater rapport and compliance. For example, a patient who seeks treatment for self-inflicted lacerations but who will not cooperate with a history aimed at assessing suicidal risk is often more candid after the physician has rendered appropriate wound care in a nonjudgmental way.

Structure the Interview

Setting self-imposed time limits for contact with difficult patients helps control the anxiety associated with falling behind in a busy ED. Flexibility in the structure of the assessment may be necessary. It is fair and appropriate to tell the patient of the need to excuse oneself to care for other patients. The fulfilled promise of returning to complete the next element of the assessment helps build trust and rapport.

Set Limits

It is helpful to share the ground rules of reasonable behavior with patients. For example, profane patients should be reminded that they are entitled to treatment but that their language may offend other patients. The physician may suggest they censor their remarks or be escorted from the area.

Point Out Impasses

At times, patient expectations and physician limit setting produces an impasse. When this occurs, it may be necessary to agree to disagree. Some issues can be resolved by pointing out impasses and giving the patient a chance to help solve the problem. Impasses sometimes can be resolved if difficult issues are set aside and returned to later in the interview. This fundamental approach to negotiations is generally underutilized in the ED.

Share Your Reactions

Pointing out impasses may not be effective if a patient senses annoyance or frustration in the physician. It may be helpful at such times to share one’s feelings explicitly with the patient while continuing treatment.

Redirect the Interview

Some patients love to talk about issues unrelated to the problem at hand. Pursuing trivial or chronic complaints should be avoided. Patients often require redirection to focus on issues that have some potential for resolution. Asking them to take a chronologic approach in discussing a specific concern may help keep them on track.

Take Time Out

Physicians occasionally feel unable to contain their frustration. One should feel comfortable retreating from the room and returning when both parties have regained their composure.

Use Teamwork

Individuals who intimidate or split the staff are much more easily treated from the outset with teamwork. This is especially important with violent patients requiring restraint when a show of strength in numbers may defuse potentially dangerous situations. A more subtle, but equally important, application of teamwork is in the treatment and discharge planning of patients with complex problems who require an especially well-organized, multidisciplinary approach involving medical and support services in the community. Occasionally, if available, the benefit of a “second opinion” from an emergency medicine colleague can help identify the difficult patient and allow the treating physician to regain clinical perspective.

Understand the Patient’s Agenda

Sometimes physicians ask themselves, “Why is this patient here?” It is often productive to ask the patient the same question in a nonjudgmental fashion. The patient may have an easily satisfied, although unanticipated, agenda. This may be as simple as needing a bus ticket to get home or reassurance that there is no immediate danger of dying from some minor disorder. When the patient’s needs are not as easily met, a clear understanding of the purpose of the visit may allow the opportunity to set more realistic goals.

Dealing with Negative Reactions

Although negative reactions make dealing with difficult patients an unpleasant experience, they can also provide valuable diagnostic information. Physicians should accept these reactions as understandable responses to a patient’s unpleasant behavior and use them to their advantage. Physicians typically have similar reactions to certain patient behaviors. The variations in these reactions depend on the individual physician’s personality style, previous experiences, and unrecognized prejudices. Physicians must know their own reactions to specific behavioral patterns to use them as diagnostic aids.

Early recognition of these reactions may, in addition to their diagnostic value, allow the physician to analyze them...
as the first step in preventing failure in the therapeutic relationship.11,13

Negative Thoughts about the Patient

Negative thoughts about patients have the greatest potential to adversely affect patient care. Patients are often placed into such stereotyped categories as “drug addict,” “malingering,” or “crock.” These labels may describe individual patients more or less accurately, but the potential exists for physicians to make inaccurate and potentially dangerous assumptions based on the biases linked to these labels.

The process of assigning patients to epidemiologic categories is a normal part of clinical judgment. Certain categories are used to help define the likelihood of encountering diseases in particular patient populations, thereby influencing decisions regarding investigation, treatment, and disposition. The danger in dealing with difficult patients is that this process can result in inaccurate assumptions about patients and compromise patient care.

Inaccurate assumptions about patients based on prejudicial, stereotyped labels are called cognitive distortions. The following case exemplifies the effect cognitive distortions can have on clinical decision-making.

An injection drug user requests analgesia for severe neck pain after minor trauma. The physician labels the patient a drug seeker and assumes the complaints to be fictitious. After becoming aware of the physician’s assumption, the patient becomes belligerent and aggressive. He is escorted from the ED by security. A few days later, he returns with quadriparesis resulting from a cervical epidural abscess.

The physician assumed the patient was malingering because of past experience with injection drug users and did not consider other legitimate explanations for the patient’s behavior. This phenomenon, known as “all-or-none” thinking, leads to the real disease being overlooked.

Negative Self-Perceptions

Self-directed negative thoughts by physicians often reflect a sense of inadequacy or despair. Some patients contribute to the problem by criticizing their care in ways that reinforce the physician’s feelings of inadequacy. Unreasonable expectations of patients, coupled with their secret conviction that no one can really help, combined with the all too prevalent rescue fantasies of physicians, create a potent recipe for physician frustration, which in the long term can contribute to eventual burnout.

Negative Behaviors

Physician behaviors can be the most obvious manifestations of negative feelings and thoughts. Examples include rudeness, sarcasm, and indifference toward patients. A patient may receive an incomplete clinical evaluation, and unnecessary ancillary tests may be performed, as an attempt to compensate. Physical or chemical restraint use, administration of naloxone, or the performance of other procedures may be used inappropriately or punitively. Analgesics may be withheld or used sparingly. Faulty communication may result in misunderstood discharge instructions and poor compliance. Impaired patient-physician relationships may lead to a refusal of care, forcing treatment against patients’ wishes, or resulting in them leaving against medical advice.11

Although patients can suffer at the hands of physicians, the potential exists for the reverse to occur. Dissatisfied patients with incorrect diagnoses and poor follow-up instructions are prone to initiate successful malpractice suits against physicians.1 The physician may become the victim of patient violence.22 Negative physician behaviors can also have an effect on the rest of the ED staff. Actions viewed by colleagues as inappropriate can compromise team morale and functioning. Physicians who are feeling angry, demoralized, and stressed may vent their frustrations on team members or consulting services, resulting in a further deterioration of the immediate situation and potential damage to long-term working relationships.

Strategies for Managing Negative Reactions

Six strategies are helpful in managing physicians’ negative reactions toward patients.

Maintain Appropriate Emotional Distance

Physicians should avoid reciprocating hostile reactions offered by patients. This may be difficult to resist and is best accomplished by maintaining sufficient emotional distance so as to avoid taking the patient’s behavior personally. This “detached concern” must be balanced with sufficient emotional investment to convey a sense of caring and empathy for the patient.11

Generate Alternatives to Negative Reactions

Instead of applying negative labels, physicians should attempt to view the patient as a victim of circumstance. Patients do not choose the social and genetic pool into which they are born. They do not choose to be abused children, to suffer from psychiatric disorders, or to experience many of the life events that lead to an ED visit. They are entitled to high-quality care, delivered with courtesy and empathy, despite their behavior.

Attempt to Understand the Patient’s Behavior as a Symptom

The second step in managing negative reactions is to recognize that patients relate to the world in a particular way because of their condition, culture, and circumstances. The condition may include a variety of medical and psychiatric problems, intoxication, cognitive impairment, or personality disorders or traits. The behaviors that one finds so disturbing should be recognized as the symptoms resulting from these conditions. Cultural differences and social circumstances can result in behaviors that seem irrational or difficult if the underlying issues are not understood. When attempting to maintain a compassionate approach to a particularly troubled and troubling patient, it is sometimes helpful to imagine how difficult one would find it to be that patient.

Look for the Cognitive Distortion

Cognitive distortions are best identified by looking for evidence that patients or situations are being stereotyped. Physicians should be aware of the effects on clinical judgment that arbitrary inferences and all-or-none thinking have on interactions with patients.23

Find a Rational Response to Cognitive Distortions

The initial reaction to the elderly schizophrenic patient presenting with chest pain might be to discount the symptoms as delusional. Psychosis, however, is not protective against ischemic heart disease, and the principle of first considering the
most potentially life-threatening diagnosis serves both the patient and physician well in the ED.

### Place Negative Reactions in Perspective by Viewing Them in Context

The ED is a stressful work environment. An expectation exists that emergency physicians will deal with problems quickly and effectively. Patients who thwart physicians’ attempts to perform accordingly may be identified as undesirable. Such patients are difficult to view objectively when one is feeling overwhelmed. The frustration resulting from dealing with such difficult situations may produce an exaggerated response to a patient’s behavior. Recognizing this may help reduce the loss of objectivity that leads to problems with patient care.

Although dealing with negative reactions is not the panacea for dealing with difficult patients, it provides the foundation for restructuring one’s interactions with them in a way that will ultimately benefit the patient clinically and the physician emotionally.

### Crisis Intervention

Some presenting complaints such as “can’t sleep,” “nervous stomach,” “anxiety,” and “can’t cope” are especially likely to produce a sense of frustration and dread among caregivers. Attempts to deal with such complaints directly often prove unfruitful, partly because the patient’s seemingly exaggerated affect interferes with effective communication. These are, however, all signs of a patient presenting in crisis.24

#### Anatomy of a Crisis

A crisis occurs when a hazardous event is encountered and customary problem-solving strategies prove ineffective.24 People experience crises of various intensities many times in their lives; common examples include the death of a loved one, the loss of a job, serious illness, and domestic violence. The usual response of an individual to such stress is to experience an inner tension that mobilizes coping skills. Different problem-solving behaviors are then tried based on previous experience.

If an effective means of resolving the crisis is chosen, the person returns to a more organized state. If a resolution to the crisis is not easily found, a period of disorganization follows. During this time, the person experiences intense emotions such as confusion, anxiety, fear, anger, and despair. It is during the state of emotionally charged disorganization that a person may seek help at the ED.

Patients in crisis will, by the nature of their complaints and behavior, fall into the category of “the difficult patient” whether or not they actually are a “difficult person.” It is important to be able to apply certain techniques of crisis intervention when dealing with such patients.

#### Dealing with the Crisis

**Recognizing the Crisis.** The presenting complaint of a patient in crisis may be a description of an event, situation, emotion, or physical symptom that can be vague or specific (domestic violence, inability to cope, anxiety, unwell, headache). Patients who present with crisis-related symptoms are a heterogeneous group. At one end of the spectrum are patients who have chief complaints that describe some type of emotional suffering and who do not require a traditional “medical” workup. At the other extreme are patients who need to be reassured in absolute terms about the absence of serious disease before their anxiety is alleviated. Between these two extremes are patients who partially understand how their circumstances might be contributing to their suffering. They can accept the idea that “the effect of stress often produces these kinds of physical symptoms.” Many patients, however, are justifiably unwilling to accept this explanation until they believe their medical complaint has been adequately assessed. This usually requires no more than a careful history and physical examination followed by reassuring communication from the physician, and the patients’ perception that the complaint is taken seriously. Some patients who are in severe crisis need to be taken through the steps of formal crisis intervention. The complex nature and considerable time required for this are often beyond the scope of practice of a busy emergency physician. The unfortunate increase in the length of stay for psychiatric patients in the ED, due to diminishing resources for these patients, may provide an opportunity for social workers, psychiatrists, or psychiatric nurse practitioners to employ this technique. A recognition of the patient in crisis is critical to creating a functional patient-physician relationship, addressing their underlying illness, and beginning the process of intervention (Box 189-2).

**Gathering Basic Information.** The first step in crisis intervention, after recognition of the crisis, involves gathering general information about the patient’s home environment, work situation, personal relationships, and social involvements. The purpose of basic information gathering is to place the patient and the crisis into context before exploring the crisis itself. This step is time-consuming and cannot be rushed, and it needs to be performed by providers other than the emergency physician.

**Understanding the Development of the Crisis.** A structured interview is performed to obtain information about the sequence of events leading up to the crisis and the nature of the crisis itself. The objective is to understand the situation while keeping the interview organized and directed so that the patient can describe events without being overwhelmed by the emotion attached to them.

**Reproducing the Peak Tension of the Crisis.** Once the crux of the crisis is identified, the care provider should proceed to help the patient express the intense emotions associated with the situation. Through empathetic, active listening, the person in crisis is allowed to experience the previously overwhelming emotions in a safe context. This places the care provider in a position of trust and sets the stage for problem solving.

**Finding the Solution.** In the final phase of crisis intervention, the physician reframes the circumstances in objective, realistic, and understandable terms for all those concerned in order to facilitate a solution to the problem. Possible solutions to the crisis are then suggested, with participation from the involved parties, and the best plan for resolution is implemented. It is important that this be a joint effort and that the patient have some ownership of the solution.24

### SPECIFIC APPROACHES FOR DEALING WITH DIFFICULT PATIENTS: PUTTING IT ALL TOGETHER

The various management strategies described here can be consolidated to formulate a practical approach to dealing with
difficult patients. The first step is the recognition of specific behavior types, rather than traditional diagnoses. These behavior types describe the most difficult patients seen in the ED. Patients displaying some, but not all, characteristics of a certain behavioral type may still be amenable to the management strategies for that type.

**Behavioral Classification**

Individuals with personality disorders frequently present as difficult patients. Although reliably establishing the diagnosis of a personality disorder during the typical brief ED encounter is difficult, an awareness of those personality disorders having a high prevalence in the ED helps ease communication with colleagues when the diagnosis has been previously established (Box 189-3).

An alternative to the traditional diagnostic categories for classifying difficult patients is based on four specific behavioral presentations and the negative reactions they produce. We have adapted this classification system, using more neutral terms. The behavioral categories are dependent patients, entitled patients, intractable patients, and self-destructive patients. Through recognition of the difficult patient's maladaptive behavior and identification of the physician's subsequent negative reactions, patients can be placed into one of these behavioral categories. The behavioral categories in turn suggest effective treatment strategies for each patient type (Table 189-1).

**Dependent Patients**

Dependent patients see physicians as inexhaustible sources of compassion and understanding. Their initially reasonable requests rapidly escalate into repeated demands for reassurance, affection, analgesia, or other forms of attention. They are excessive in their gratitude; however, the more care they receive, the more their needs multiply. Initially, the physician

---

**COMMONLY ENCOUNTERED PERSONALITY DISORDERS**

**Borderline Personality Disorder**

Pattern of instability of interpersonal relationships, self-image, and affect that is accompanied by marked impulsiveness beginning by early adulthood and present in a variety of contexts. It may be indicated by five or more of the following:

1. Frantic efforts to avoid real or imagined abandonment
2. A pattern of unstable and intense interpersonal relationships characterized by alternating extremes of idealization and devaluation
3. Identity disturbance: markedly and persistently unstable self-image or sense of self
4. Impulsiveness in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating)
5. Recurrent suicidal behavior, gestures, threats, or self-mutilating behavior
6. Affective instability caused by a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

**Antisocial Personality Disorder**

Pattern of disregard for and violation of the rights of others since the age of 15 years as indicated by three or more of the following:

1. Failure to conform to social norms with respect to lawful behavior as indicated by repeatedly performing acts that are grounds for arrest
2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
3. Impulsiveness or failure to plan ahead
4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults
5. Reckless disregard for safety of self or others
6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another

**Dependent Personality Disorder**

Pattern of pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation beginning by early adulthood. It may be indicated by five or more of the following:

1. Difficulty in making everyday decisions without an excessive amount of advice and reassurance from others
2. Needs others to assume responsibility for most major areas of his or her life
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval
4. Has difficulty self-starting projects or doing things (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy)
5. Goes to excessive lengths to obtain nurturing and support from others, to the point of volunteering to do things that are unpleasant
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for self
7. Urgently seeks another relationship as a source of care and support when a close relationship ends
8. Is unrealistically preoccupied with fears of being abandoned

**Paranoid Personality Disorder**

Pattern of distrust and suspiciousness of others, such that their motives are interpreted as malevolent, beginning in early adulthood as indicated by four or more of the following:

1. Suspects, without sufficient basis, that others are being exploitative, harmful, or deceitful
2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
4. Reads hidden demeaning or threatening meanings into benign remarks or events
5. Persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights)
Commonly Encountered Personality Disorders—cont’d

Histrionic Personality Disorder
Pattern of excessive emotionality and attention seeking beginning by early adulthood as indicated by five or more of the following:
1. Is uncomfortable in situations in which the center of attention is someone else
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
3. Displays rapidly shifting and shallow expression of emotions
4. Consistently uses physical appearance to draw attention to self
5. Has style of speech that is excessively impressionistic and lacking in detail
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
7. Is suggestible (i.e., easily influenced by others or circumstances)
8. Considers relationships to be more intimate than they actually are

Narcissistic Personality Disorder
Pattern of grandiosity, need for admiration, and lack of empathy beginning by early adulthood as indicated by five or more of the following:
1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
3. Believes self to be “special” and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
4. Requires excessive admiration
5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with their expressed expectations)
6. Is interpersonally exploitative (i.e., takes advantage of others to achieve personal ends)
7. Lacks empathy, is unwilling to recognize or identify with the feelings and needs of others
8. Is often envious of others or believes that others are envious of him or her
9. Shows arrogant, haughty behaviors or attitudes

Entitled Patients

Entitled patients also seem to have endless needs, but instead of helplessness or seduction, they use intimidation, hostility, and threats to attain their often unreasonable demands. Entitled patients fear being helpless and dependent on physicians. They use a shield of entitlement to protect themselves. An example is the lawyer who, in his refusal to accept his illness, roams from physician to physician demanding repeated tests and opinions, while threatening to sue the previous physician who had tried to help him. Physicians experience the natural responses of disgust, anger, and antagonism when faced with such patients. There may be an urge to enter into a power struggle with the patient. The other common temptation is to accept the patient’s terms at the price of compromising his or her care. Occasionally, the physician may even experience shame at being unable to meet the patient’s unrealistic demands. The maladaptive behaviors of entitled patients are commonly seen in people with paranoid and narcissistic personality disorders, as well as in addicted patients and VIPs.

Because the behavior of the entitled patient stems from insecurity, it is important to be supportive. While reassuring patients that they are entitled to good medical care, physicians must set limits that unreasonable demands will not be met. Prolonged debates with the patient about diagnostic and therapeutic options should be avoided. Recommendations about management options should be offered and patients left to

Dependent patients are especially likely to seek solutions to their problems at the ED in times of crisis. Looking for the underlying issues and structuring the interview along the lines of crisis intervention can assist in finding a satisfactory resolution to the patient’s problem.

VIPs, very important persons.

Exercise their autonomy in choosing their preferred course. At the same time, physicians must communicate their acceptance of the patients' rights to exercise this control and that their decision will not jeopardize subsequent access to appropriate care.

**Intractable Patients**

Intractable patients, like dependent and entitled patients, have insatiable needs for emotional support. They are, however, neither seductive nor dependent in their behaviors. They present the antithesis of entitlement; they believe nothing will help. Intractable patients desperately seek help despite the failure of all previous medical assistance. Their history is punctuated by multiple emergency visits and behaviors that are self-defeating, covert, and manipulative. These negative behaviors undermine treatment and antagonize physicians, creating feelings of anger, self-doubt, and frustration. Patients with borderline and antisocial personality disorders and malingers often fall into this behavioral category.

Malingers are among the most difficult patients presenting to the ED. Malingering is the intentional production of false or grossly exaggerated physical or psychiatric symptoms, motivated by external incentives that are unrelated to illness. These patients may be seeking narcotics, shelter, or monetary compensation; may be attempting to avoid work or criminal prosecution; or may simply be lonely.

Malingering represents deceptive, manipulative behavior and is coded in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), as a “problem” rather than a mental disorder. This contrived behavior must be distinguished from the psychiatric illness of somatoform disorders. Somatization is the involuntary production of symptoms without the patient's awareness. Unlike malingers, somatizers are not motivated by any conscious desire for secondary gain.

Repeaters are patients who frequent the ED excessively to the point that most staff know them by name. Although chronic schizophrenics often fall into this category, this behavior can occur in any patient with poor coping skills and maladaptive responses to psychosocial stressors. The easy accessibility of the ED often makes it the only support system immediately available to chronically decompensated patients. Despite the perception that “frequent flyers” are often inappropriate in their ED utilization, studies demonstrate that frequent users...
are in poor health and require medical attention more often than less frequent users.28,29

Geriatric patients with multiple medical problems and those abandoned in the ED by caretakers who are no longer willing or able to meet their needs are also patient types that deserve special attention. Although these patients have problems that are often difficult to solve, the patients themselves are not necessarily difficult people.30

Intractable patients elicit strong negative reactions from physicians and are sometimes identified by the feelings of futility that they produce in their caregivers. Their multiple, vague complaints that defy diagnosis and successful treatment often cause them to be labeled as “crock,” along with dependent patients.

Intractable patients pose a particular risk of missed diagnosis or premature discharge. Physicians must avoid the temptation to overreact with cognitive distortions and dismiss the possibility of genuine illness in the patient. Intractable patients should be distinguished from other complicated patients, evaluated for conditions that require immediate intervention, and provided appropriate management and disposition. Alternatively, there may be a tendency to inappropriately launch into extensive investigations if the behavior type is not recognized. Collateral information from previous medical records and other caregivers is valuable in providing diagnostic guidance.

Because this type of behavior stems from a need for a relationship and fear of rejection, it is important for physicians to be supportive. The belief that showing empathy only encourages maladaptive behavior is generally untrue. To the contrary, an escalation of symptoms usually follows when these patients interpret a physician’s lack of concern as rejection.

Nevertheless, limits should be set regarding patients’ expectations. Physicians should use this strategy while acknowledging the difficulty of the patients’ problems and sharing their deep concern, and perhaps even pessimism, regarding the outcome of the investigations and treatment. It is helpful to make statements such as, “You know, Mr. Jones, you obviously have a very difficult problem here. You’ve seen lots of doctors and had lots of tests and treatments that don’t seem to be helping much. There is no way, given the limited resources available in the ED at 11 o’clock on a Friday night, that we are going to be able to get to the bottom of this. What I can do is examine you and do some tests to make sure that there is no new, serious problem going on tonight. Then you will be able to follow up with your regular doctor on Monday.” In this way the physician can communicate both an interest in the patient and empathy for his condition while setting limits on expectations. Both the physician and patient then understand the “contract” and have a way of terminating the encounter satisfactorily.20

Self-Destructive Patients

Self-destructive patients are particularly difficult to treat. Unlike intractable patients, they do not seek help. Rather, they are repeatedly brought to the ED because of their neglectful and self-destructive behaviors. Their ability to deny their problems is profound and sets up the maladaptive cycle of “nothing is wrong and nothing will help.” Yet their behaviors often require repeated heroic efforts to save their lives. Their chronic self-destructive behaviors may temporarily meet their immediate needs of shelter and food and perhaps, paradoxically, some of the attention they outwardly reject. This lethal cycle usually leads to a premature death. The substance abuser, the violent patient, and the suicidal patient are included in this category of difficult patient.10

It is not surprising that ED staff respond to such patients negatively, feel frustrated and helpless, and may even secretly wish them success in their self-destructive efforts. These are among the most difficult patients to treat. In reality, physicians can do little apart from providing appropriate care for the multiple presentations characteristic of this type of patient. The greatest obstacle for physicians may be to come to terms with their own complacency about the survival or demise of such patients. The lack of real concern about whether they live or die or, worse, actually wishing that they would die, is repugnant and produces feelings of self-recrimination. Our inability to relate to the self-destructive decisions made by these individuals contributes to our complacency about their plight. Remembering our own human weaknesses or risk-taking behaviors and viewing their seemingly incomprehensible behavior as a difference in degree rather than in kind may help us to have more empathy for them.11 Being supportive is important. Signs of depression in the patient may indicate the need for psychiatric referral. These patients should be screened for risk of suicide and, when appropriate, held for psychiatric evaluation following medical stabilization.

### SUMMARY

Dealing with difficult patients is a common problem in the ED. The impaired patient-physician relationships associated with them have multiple negative implications for both patients and physicians. Their treatment may be optimized by using the general principles discussed in this chapter, by dealing realistically with one’s own negative reactions, and by using techniques of crisis intervention where appropriate. These strategies are best applied within the context of a behavioral classification that avoids pejorative terms and stereotypes, labels that differentiate them from “worthier” patients.11 Although this approach is not a panacea for dealing with difficult patients, the framework may help physicians render appropriate care while minimizing personal frustration, medicolegal exposure, and eventual physician burnout.

One of the great challenges of medical practice is to maintain humanity when caring for these difficult and highly vulnerable individuals. By focusing on their humanity, we have the best chance of preserving our own.11 It is easy to care for patients who generate sympathy and noble to care for those who do not.13

In the end, the ability to accept distressing behavior as a symptom and to treat even the most irritating individuals with compassion and kindness may be the key to surviving them. When asked how he had avoided burnout after decades in emergency medicine, one well-known patriarch of the specialty simply responded, “You’ve got to love the patients.”14 This is a tall order, and not meant in the literal sense. But the degree to which we can show caring and empathy, even to the unlovable, may be the key to maintaining the quality of our care, our satisfaction with the specialty, and our long-term survival in practice.
### KEY CONCEPTS

- Difficult patients may elicit negative reactions in caregivers, resulting in undesirable implications for both themselves and their caregivers.
- Managing the difficult patient can be optimized by understanding the multiple factors contributing to the impaired physician-patient relationship.
- Behavioral classifications should be used instead of pejorative stereotypes when characterizing difficult behaviors.
- General and specific strategies, including understanding our own reactions, are helpful in dealing with the impaired physician-patient relationship.
- The ability to accept difficult behaviors as symptoms and treat even the most difficult patient with kindness is central to providing good care while avoiding personal frustration, medicolegal repercussions, and physician burnout.

Emergency Medical Services
Hospital. years later, the first city service began at New York’s Bellevue established the first hospital-based ambulance service. Four used today. In 1865, the Commercial Hospital in Cincinnati used during the American Civil War, and a modern ambulance lance used during the Napoleonic Wars, the Rucker Wagon field defibrillation programs in Belfast, Northern Ireland, and develop a program for improving emergency medical care. National Highway Traffic Safety Administration (NHTSA) to directed the U.S. Department of Transportation (DOT)—efforts were the impetus for congressional legislation that building blocks for future EMS maturation. These national emergency care provision at all levels and outlined the necessary this document described the hazardous conditions of emergency Neglected Disease of Modern Society.” Published in 1966, white paper entitled “Accidental Death and Disability: The Sciences—National Research Council were used to draft a decrease death and injury from highway accidents. Results from a second national survey by the National Academy of services of care provision, including injury prevention, primary and definitive care, and rehabilitation services.

More than 40 years since publishing the 1966 white paper, the IOM released a report on the status of emergency care entitled “The Future of Emergency Care in United States Health System.” The report focused on three separate, yet related, topics: (1) emergency care: at the breaking point, (2) emergency medical services at the crossroads, and (3) emergency care for children: growing pains.

A major focus included the need to strengthen the integration of EMS into the entire healthcare system, because lack of such coordination often results in patients being diverted from overcrowded to inappropriate or distant facilities. The recommendation was to ensure that the delivery of emergency medical and trauma care is organized into a coordinated, regional system such that patients receive care at the most appropriate facility based on their injury or illness. Additional recommendations targeting EMS improvement included national accreditation for paramedic educational programs, adopting a national certification system for individual state license, and recognizing common levels of EMS certification across the United States.

The concern for inadequate funding for EMS systems operations and disaster response was also addressed. Recommendations included Congress developing regionally funded, multiyear demonstration projects that encourage states to identify and test strategies for creating seamless systems of care, workforce strengthening, evidence-based practices, and disaster preparedness. It was further recommended that an advisory committee be created to work with the Centers for Medicare and Medicaid Services to improve reimbursement and policies related to reimbursement.

Finally, a small, yet significant, proportion of EMS transports involve the pediatric population; thus, it is often difficult for prehospital providers to maintain the knowledge and skills necessary to care for critically ill or injured children. Many plans, including disaster preparedness, often neglect children. As such, the IOM report recommended several items, most importantly that the care of children be integrated into the overall EMS system and not separated from adults, with pediatric emergency care competencies being defined and training enhanced to maintain those competencies.
Emergency Medical Service Systems

Multiple EMS system designs exist, all predicated on the type of community served. While this is a local decision, all states incorporate an administrative office that governs or oversees the provision of EMS activities. Typically the role is not to direct any individual service, but to assist in planning, licensing services, and establishing or enforcing the scope and standards for practice. Other functions may include training, examining, certifying and recertifying providers, record keeping, data collection, and auditing or investigating programs. A description of systems for the 200 most populous cities in the United States is periodically published in the Journal of Emergency Medical Services.14 For simplicity, the following categorization of systems will be used: private and public agencies; basic life support (BLS) and advanced life support (ALS) services; and single-tiered, multitiered, and first responder systems.

Private and Public Agencies

Where local government has not assumed primary responsibility for EMS services, communities may depend on private providers. Financial responsibility varies but usually depends on federal reimbursement (Medicare or Medicaid) and user fees. A local government subsidy may or may not supplement the operation. If multiple providers are serving one jurisdiction, calls may be allocated by rotation or specified zone coverage. Dispatching varies depending on the system but may be by the provider or by a central agency. Medical direction is often provided by a contracted physician or physician oversight board.

Hospital-based EMS systems are few in number and may be managed by a single hospital or hospital corporation. Not all hospital-based EMS programs are considered private, in that the hospital may be a division under local or state government or operating under a public authority. Like private models, financial responsibility is usually in the form of user fees, with or without additional subsidy. Dispatching may be provided by a local public safety agency that may also be responsible for police and fire communications. An emergency physician from a sponsor or base hospital typically provides medical direction for these systems.

A public utility model is a hybrid between private and public design that allows local government to contract with a private or public provider. The successful bidder for service becomes a contracted entity that agrees to provide the specified services (ALS, BLS, or both) to the catchment area and, depending on the arrangement, may bill the patient directly or receive uniform reimbursement. Depending on local structure and interagency agreement, dispatching may be performed by an existing public safety organization or by the parent company. Medical direction is usually a specified individual subject to contractual terms.

When government officials were faced with planning and establishing EMS systems during the early maturation periods, many decided that the fire department was the logical choice to incorporate EMS. Fire stations were strategically located throughout the community, and personnel were already used to providing emergency response. Firefighters could be cross-trained as a firefighter-paramedic or dedicated to either fire or EMS function with the opportunity for transfer. Public EMS systems that were not incorporated into fire departments evolved into their own separate entity, referred to as a municipal third-service system. Such agencies are operated by local municipalities and are endorsed and supported by local government. Many cities have been successful in combining...
police, fire, and EMS under a global public safety agency, with all department heads or chiefs reporting to one manager or administrator. Financially, public EMS systems may be supported by a tax base, which may or may not be supplemented by user fees. Regardless of design, medical oversight for a municipal EMS system may be provided by a physician appointed and contracted by a local hospital, an advisory council, or a medical oversight board.

**Basic Life Support and Advanced Life Support Service**

BLS describes the provision of emergency care without the use of advanced therapeutic interventions. Skills include airway management (oral and nasal airways, bag-mask ventilation), cardiopulmonary resuscitation (CPR), hemorrhage control, fracture and spine immobilization, and childbirth assistance. Defibrillation using an automated external defibrillator (AED) is often included by many BLS systems. Services are provided by certified or medical first responders or emergency medical technicians (EMTs) certified at the basic level (EMT-B).

BLS systems may be associated with poor survival rates from out-of-hospital cardiac arrest, especially those not incorporating AED technology. Alternatively, there is debate on the effectiveness of ALS for medical and traumatic emergencies. Despite this evidence, few urban communities across the United States operate solely at the BLS level. Many rural and some suburban EMS services rely on volunteers who may not wish to become advanced-level providers. Because these services may have low call volumes, it becomes more difficult for personnel to maintain advanced skills and a proficient knowledge base. Also, such communities may not have access to medical supervision or hospital sponsorship for ALS care.

Systems categorized as ALS offer a more comprehensive level of service by highly educated providers, usually certified at the intermediate or paramedic level (EMT-I or EMT-P, respectively), or equivalent levels depending on individual state certifications. Provider skills include advanced airway interventions, intravenous (IV) line placement, medication administration, cardiac monitoring and manual defibrillation, and certain invasive procedures. Most EMS systems in urban cities operate at the ALS level of care.

The number of EMT-Ps in any jurisdiction has come under scrutiny, in that cities with more paramedics per capita tend to have lower survival rates. Although this may seem implausible, one explanation might be that the number of patient encounters per paramedic decreases and the sharpness of skills degrades when that community is saturated with paramedics.

**Single-Tiered, Multitiered, and First-Responder Systems**

In a single-tiered system, every response regardless of the call type receives the same level of personnel expertise and equipment allocation (all BLS or ALS). Multiple-tiered systems use a combination of ALS and BLS levels depending on the nature of the call. Differences in cost and effectiveness between a mixed ALS-BLS service and an all ALS service have been debated. Currently, there is a steady decrease in systems that provide mixed ALS-BLS care. A single-tiered ALS response may prove to be cost-effective in specific locales, ensures the capability of providing a consistent advanced level of care to all patients regardless of illness or injury severity, and obviates the potential for undertriage or overtriage by 9-1-1 telecommunications. Alternatively, a multitiered system may meet the needs of individual communities or agency infrastructure. This design often meets with employee satisfaction and has the potential to preserve ALS resources for higher priority calls, in that BLS transport of nonurgent patients allows for ALS ambulances to be available for potential critical responses.

Regardless of single- or multiple-tier design, EMS systems usually include first-responder (FR) services as part of their structure. The FR, usually a police officer or firefighter, is the nontransport BLS or ALS provider who quickly responds to the scene of an emergency to provide initial care before definitive medical care and transportation assets arrive. The FR quickly assesses the situation and patient(s), determines whether additional resources are required, initiates patient care, and provides advance information to responding personnel.

The design of an EMS system is targeted toward providing quality patient care in the briefest period of time following unexpected injury or illness. A desirable and cost-effective design might include BLS nontransport FRs with short response times (average 2–4 min), having the capability of providing early defibrillation and airway support, coupled with ensuing ALS care and transport services.

**Levels of Provider and Scope of Practice**

At the federal level, NHTSA is responsible for developing the National Standard Curriculum for the different certification levels. Individual state legislation is responsible for provider levels recognized, initial and continuing medical education requirements at each level, testing, and time intervals for course completion and recertification. The following sections outline the DOT recommendations for the four common levels of provider with suggested hours of training and incorporated skills (Table 190-1).

**First Responder**

The FR is typically the first to arrive on the scene of an incident. Initial scene and patient assessment, along with limited life-saving interventions, are primary functions. Along with CPR and basic airway management skills, the FR should be able to control hemorrhage and initiate spinal immobilization.

The four elements referred to as the “chain of survival” by the American Heart Association (AHA), which decrease mortality from out-of-hospital cardiac arrest, are early access to care, CPR, defibrillation, and advanced airway management and medications. Because early defibrillation may improve the odds of survival of out-of-hospital cardiac arrest, the use of an AED should be a mandatory procedure for the FR.

The DOT recommends 40 hours of didactic instruction for the standard FR course and 16 to 36 hours for refresher training. A clinical rotation is not part of the curriculum.

**Emergency Medical Technician—Basic**

The EMT-B is the minimum level required to staff a BLS ambulance and is commonly used for nonemergency and convalescent transport services. In addition to the skills of the FR, the EMT-B is also involved with triage, more detailed patient assessment, and transportation. Like FRs, EMT-Bs should have the capability of providing early defibrillation.

In 1995, NHTSA released the revised EMT-B curriculum. The initial course requires approximately 110 hours of instruction and includes 46 lessons, each with cognitive, effective, and psychomotor objectives. Many states have expanded the course to include more skills such as AED use, epinephrine autoinjections, albuterol administration by hand-held nebulizer or metered-dose inhaler, and IV fluid therapy. For recertification, the DOT recommends a 24-hour refresher course,
48 hours of continuing education, and a BLS course every 2 years.

Emergency Medical Technician—Intermediate

The EMT-I was established to allow a more comprehensive approach to care when paramedic services were unavailable or unobtainable. Many states recognize the EMT-I certification, but others designate alternative, but comparable, levels depending on specific skills and procedures. The intermediate level is useful for rural systems because it supplies an ALS for less cost and educational time expended. The scope of practice for the EMT-I varies across the United States. Most systems allow the EMT-I to establish an IV line and to manually defibrillate. Limited administration of medications and use of adjunctive airway devices (e.g., blind insertion airway device or laryngeal mask airway) may be integrated skills.

The DOT recommends 300 to 400 hours of initial education that includes didactic classroom lectures combined with hospital and field experiences.30

Emergency Medical Technician—Paramedic

The EMT-P is the most advanced out-of-hospital provider. Paramedics have the capability to address most out-of-hospital emergencies. The scope of practice includes a wide variety of therapeutics and procedures including cardiac rhythm recognition, expanded pharmacologic treatments, and advanced airway interventions. Other important invasive procedures include needle decompression of a tension pneumothorax, needle or surgical cricothyotomy, and transthoracic cardiac pacing.

A recent revision of the National Standard Curriculum for the EMT-P calls for approximately 1000 to 1200 instructional hours, including didactic, clinical, and field education. All course content focuses on technical and professional competency. Additional modules are included that allow programs to incorporate an expanded scope of practice.31 With the expansion of EMS technology and management career options, many paramedic educational programs have advanced from 1-year certificate curriculums to 2-year associate or 4-year baccalaureate degrees. Recertification requirements include a 48-hour refresher course, 24 hours of yearly continuing education, and BLS and ALS courses at the pediatric and adult levels.

Material Resources

Prior to the mid-1960s, few if any regulations governed system design, operations, and equipment. As EMS development progressed, guidelines for emergency vehicle specifications were adopted by the DOT and equipment lists were proposed. Today, the American College of Surgeons, the ACEP, and the EMS-C Program continue publishing documents that recommend design, equipment, and medications for ambulances.32,33

Medications

During the 1980s, many believed that prehospital drug administration was unjustified and simply delayed hospital transport.34,35 Moreover, there is a profound paucity of outcomes-based research into the use of various medications in the out-of-hospital environment.36 There is significant evidence for early defibrillation and certain advanced cardiac life support medications, which are carried by most ALS services.37 The wide variety of alternative medications is less uniform. This includes respiratory and anaphylaxis medications, preparations for altered mental status, analgesics, and antiemetics. Medications are traditionally administered in the field by the parenteral route, but the intranasal route is becoming popular for certain preparations. The beneficial aspects are that absorption is rapid with an onset of action similar to parenteral administration. Two medications that are commonly administered intranasally are naloxone for narcotic overdose and midazolam for pediatric seizure.38,39

AED, automated external defibrillator; ALS, advanced life support; BLS, basic life support; CPR, cardiopulmonary resuscitation; DOT, Department of Transportation; EMT, emergency medical technician; IV, intravenous.
Equipment

Basic ambulance equipment should include items necessary for emergency procedures (i.e., airway support, hemorrhage control, fracture and spine immobilization, childbirth), personal protection, patient movement, and basic rescue procedures. Additional patient care equipment is predicated on the level of provision outlined by the system design.

Ambulances

Three basic ambulance vehicle designs are recognized by the DOT: type I, type II, and type III. Both type I and type III ambulances incorporate a modular patient compartment mounted on a conventional truck and van chassis, respectively. The type II vehicle is a standard van. The larger medium-duty vehicle, mounted on a business-class chassis, has become popular in recent years. This configuration requires less periodic maintenance and offers extended service time. Each ambulance manufacturer promotes various interior cabinetry and all include sufficient lighting, outlets for 110-volt equipment, suction, oxygen systems, and external audible and visual warning devices. The six-pointed blue star, or “Star of Life,” surrounding the staff of Aesculapius is recognized worldwide as the standard symbol for EMS.40

Communications

Integral to out-of-hospital care systems, EMS communications involve multiple components, all interlinked to support expeditious patient care. Effective communication systems include public information and education programs regarding general access to care, technology to ensure simplified access, means of call prioritization and management of available resources, protocols for providing emergency patient care instructions prior to EMS arrival, ability to communicate with allied agency and hospital personnel, educational opportunities for telecommunicators, and quality improvement processes.

Access

Since 1973, the 9-1-1 universal emergency access telephone number has been adopted by many communities throughout the United States. Basic 9-1-1 service simply connects a caller to a central communications center or public safety answering point (PSAP). Most primary PSAPs are under the domain of law enforcement. Although many of these handle all public service (police, fire, EMS) calls, many larger cities have secondary PSAPs for fire and EMS. Enhanced 9-1-1 provides additional information by immediately displaying the caller’s telephone number and address.

Emergency Medical Dispatch

Dispatching encompasses multiple elements that assist patients in receiving expeditious medical care.41 It is estimated that 30% of EMS calls are for nonemergent conditions, with only 15 to 20% being considered critical or life-threatening.42

The emergency medical dispatcher (EMD) is responsible for ascertaining the primary medical condition and severity. Communication centers that model their dispatch response protocols on priority use a finite list of common chief complaints, each having associated predetermined questions. Answers to these questions ultimately dictate a predefined response mode. Depending on the response assigned and system configuration, an ambulance (BLS or ALS) and possibly an FR resource is dispatched to respond in an emergency or nonemergency mode. When critical conditions are identified, the EMD may proceed in giving specific prearrival instructions to assist the caller in providing critical interventions prior to EMS arrival. These include procedures such as opening and clearing an airway, performing CPR, controlling hemorrhage, and assisting with childbirth. Such assistance dramatically narrows the response time interval for receiving emergency medical care.

Systems Status Management

Depending on system size, population served, and resources available, the use of systems status management has proven beneficial for many services. Based on historical data, high-performance or peak-demand periods of the day coupled to service areas or call location can be identified so that coverage plans or posting assignments may be instituted. Such mechanisms place ambulances at predetermined locations where potential calls are likely to occur. Response vehicles may be equipped with an automatic vehicle locator that functions as a telemetry unit, or global positioning satellite system that provides a site interface with the computer-aided dispatch system. This site information is helpful when staging or redeployment of vehicles is required during periods of high call volume or when resources are limited.

Field Communications

While at the scene or during transport, EMTs usually have the capability of communicating with hospital staff. A consultative patient report may be given to receive medication or intervention orders, or simply for arrival notification. EMS providers should also have the capability of communicating with all allied public safety agencies for mutual aid purposes, mass casualty situations, or disaster responses. If air medical services are available, EMS and fire personnel must have the capability of communicating with the helicopter pilot and crew members. Scene personnel must relay landing zone information and potential hazards to the pilot and should provide a preliminary patient report to the medical crew.

MEDICAL DIRECTION

An EMS medical director is a physician with specialized interest and knowledge of patient care activities unique to the out-of-hospital environment. Medical oversight must extend from the communications center through all components of field care. Typically, a contractual arrangement for services provides the physician with administrative authority to implement patient care protocols, to interact with all aspects of the system, and to remove a provider from practice if medical care or behavior is substandard. Published guidelines describing the activities and performance of an EMS medical director have been prepared by ACEP, National Association of Emergency Medicine Services Physicians (NAEMSP), NHTSA, and Health Resources and Services Administration (HRSA).43-45

Medical direction consists of off-line (indirect) and on-line (direct) control. Off-line medical control includes protocol development, personnel education, prospective and retrospective patient care review, and other quality improvement processes. Direct medical control concerns real-time interaction between a physician or designee and the field provider.

Indirect Medical Control

Medical accountability for patient care activities is the basis for indirect medical control and functions either
before a patient is encountered (prospective) or after hospital transport has occurred (retrospective). Patient care guidelines and protocol development for EMTs and EMDs, continuing medical education, medicolegal policies, and quality and performance improvement processes are important elements.

Protocols

Perhaps the most important duty of the medical director is to develop patient care protocols. Protocols serve as pre-established practice guidelines that define the standard of care for most illnesses or injuries encountered in the out-of-hospital setting. Operational issues, such as hospital designation and destination policies, termination of resuscitation, and patient transport refusal, may be included. Depending on state regulations, protocols may include standing orders for particular clinical situations in which EMTs may perform certain procedures or administer medications for predefined patient conditions prior to communication with hospital personnel. Protocol development should be driven by system resources and patient needs and should include guidelines for triage and care of specific patient populations, including trauma patients, newborns, and children.

Regardless of local communication protocols, out-of-hospital providers should always be able to discuss a case with a physician for clarification or guidance when clinical questions or controversial situations arise. Furthermore, hospital notification is always important when critical patients are being transported.

Education

Medical directors should be familiar with and actively involved in local or regional educational programs for initial and continuing education courses for all levels of EMT certification. Course curriculum development and administration, evaluation, and revision processes should be understood. Systems that incorporate their own educational programs allow for modifications that reflect intrinsic needs of the system and the providers.

Field personnel and telecommunicators must be given regularly scheduled courses that improve competency in knowledge and skills. Instructional formats and resources to accomplish educational objectives may include didactic classroom lectures, skill labs, direct field observation, or distance learning models for self-paced opportunities. Standardized core content is important for maintaining consistency and quality of care.

Quality and Performance Improvement

Once patient care protocols are developed and implemented, there must be mechanisms, such as retrospective patient care report review or direct field observation, for evaluating individual and system performance and patient outcome. Deviations from specific protocols may reflect problems with individual EMTs, medical control personnel, or the protocol itself, each requiring education and reevaluation. Deficiencies, both operational and clinical, must be identified for appropriate remediation to occur, which may be in the form of counseling, educational instruction, or revisions of system design or patient care protocols. Competency, knowledge retention, and skill performance are measurable parameters. Time standards (e.g., out-of-chute time [time from ambulance notification to deployment], response time, and scene time) are equally important measures.

Direct Medical Control

Direct medical control is the concurrent direction of EMTs providing patient care. This may be in the form of radio or telephone communications or by direct scene observation and may be considered centralized or decentralized. In a centralized system, a selected hospital is designated as the lead facility (base station hospital, resource hospital, or sponsor hospital) and is responsible for providing all direct medical control orders and notification regardless of the receiving facility. In a decentralized system, each hospital functions as a base station, providing direction to EMTs transporting patients to its facility.

Personnel responsible for direct medical control must be knowledgeable about the entire EMS system, receiving facilities, protocols, medication formulary and equipment, administrative and operational issues, and medicolegal implications for certain presenting situations. Systems whose protocols include standing orders may only require direct communication for specific reasons. Thus, while these medical and administrative protocols may guide EMTs through most circumstances, medical control consultation may assist with medicolegal issues, situational problems at the scene, patient nontransport, or a multitude of potential ethical dilemmas that may be encountered. Nevertheless, direct medical control is usually invaluable for notifying a receiving facility for treatment room and staff preparation when critical or potentially critical patients are being transported.

OUT-OF-HOSPITAL MEDICAL CARE AND CONTROVERSIES IN MANAGEMENT

Airway Support and Respiratory Emergencies

Interventions

Respiratory complaints account for a significant number of EMS responses. Basic measures to control and support a patient’s airway include manual maneuvers (e.g., chin lift or jaw thrust), oral and nasopharyngeal devices, and use of bag-mask ventilation. At a more advanced level, interventions may include blind-insertion airway devices (e.g., Combitube or laryngeal mask airway), which have been shown to enable faster placement and provide improved minute ventilation. Studies have shown that basic-level EMTs were able to successfully place laryngeal mask airways in simulated arrest models and also demonstrated an improved minute ventilation with these devices when compared with bag-valve mask ventilations. Similar studies have demonstrated that laryngeal mask airways are more successful than endotracheal intubation for paramedics, because they provide a faster technique, require fewer attempts for successful insertion, and improve ventilation.

Commonly used by air medical services, drug-assisted intubation (DAI) and rapid sequence intubation (RSI) procedures have recently expanded in ground transport services, despite a lack of supporting evidence. Several long-standing programs have achieved great success using RSI; however, others have not appreciated the benefits and have questioned the usefulness. Several studies have challenged the effectiveness of out-of-hospital intubation, particularly in view of an alarming incidence of esophageal intubation in some systems and poor outcomes with the use of RSI for head-injured patients.

One prospective, randomized study of pediatric out-of-hospital airway management concluded that in the urban setting, bag-mask ventilation may be superior to intubation in
certain patient groups. Although controversy exists and the debate will continue, most would agree that in order to have a successful airway management program, the educational and quality management component must be meaningful and should be as comprehensive and compulsive as possible. For programs using DAI or RSI procedures, the experiential component should include operating room time and simulator sessions. Ideally, training would also occur in an ED setting where patients requiring emergent intubation would potentially have the full complement of confounding variables (e.g., combative status, full stomachs, blood and vomit in the airway).

Traditionally used in the hospital, continuous positive airway pressure (CPAP) is intensifying in the out-of-hospital setting. The effectiveness of out-of-hospital use of CPAP has been demonstrated; however, patient outcome studies have been limited. Out-of-hospital use would require strict protocols that would outline such variables as indications and contraindications, clinical applications, mental status assessment, hemodynamic status, and mechanisms for transferring the patient at the hospital.

Medications

Most advanced programs have adopted the use of clinically proven medications for bronchospasm, chronic obstructive pulmonary disease, and anaphylaxis, but no studies have demonstrated benefit to administration of these medications in the out-of-hospital environment. While some studies might be considered unethical (e.g., an out-of-hospital study of epinephrine for anaphylaxis), others (e.g., out-of-hospital use of beta2-agonists or steroids for asthma, or loop diuretics for pulmonary edema) could easily be performed, with the results far from certain. Pending further studies, most systems have adopted the position that these medications do not harm patients in the out-of-hospital setting, may be helpful, and may provide comfort and clinical improvement for most patients experiencing varying degrees of respiratory distress. The overhead related to training and maintenance of knowledge related to these additional, probably unnecessary, medications is rarely considered.

Cardiovascular Emergencies

Interventions

Previous research has demonstrated the effectiveness of early defibrillation for terminating ventricular fibrillation and improving survival rates from sudden cardiac death. Advances in technology have improved such that defibrillators, traditionally used by paramedics, are now used by a variety of public safety responders and bystanders. Public access defibrillation (PAD) programs are being implemented throughout the country, with devices being placed in high-volume, populous, and secluded areas such as airports and airplanes, casinos, and office buildings. The effectiveness of PAD is currently being investigated. The acquisition and transmission of out-of-hospital 12-lead electrocardiograms is becoming more prevalent as well. Although expensive to implement, several studies have revealed minimal delays in scene time while obtaining the ECG, and a shorter time to intervention (thrombolytic administration or catheterization lab admission) by using this technology. Although the statistics for cardiac arrest survival across the United States are dismal, those that do survive may suffer some degree of hypoxic encephalopathy. Recent evidence suggests that cooling patients who achieve a spontaneous return of circulation following cardiac arrest, especially with ventricular fibrillation as the initial rhythm, achieve higher survival rates and level of neurologic functioning. The explanation may be due to several mechanisms, including a decrease in neuronal cell oxygen consumption, cell membrane protection, slowing of degradative reactions resulting from reperfusion, and limiting acidosis. International guidelines now call for the institution of hypothermia for patients who are resuscitated from cardiac arrest, and many out-of-hospital systems have implemented protocols that may include administration of chilled saline, sedation, or neuromuscular blockers, in coordination with receiving hospital emergency departments.

Medications

Traditional cardiac medications recommended by advanced cardiac life support are used by most ALS systems. Recent investigations involving amiodarone as an out-of-hospital agent to terminate refractory ventricular fibrillation have resulted in higher survival rates to hospital arrival; however, improvement in survival to discharge is still not significant. Whether amiodarone should replace lidocaine for out-of-hospital ventricular fibrillation requires further investigation, although many systems have already made this expensive change. The use of out-of-hospital fibrinolytic agents for acute ST elevation myocardial infarction has not gained wide acceptance and may only be a useful intervention for systems having prolonged transport times, or if hospitals may not have catheterization or intervention facilities available. Future recommendations for out-of-hospital use of these agents remains speculative.

Traumatic Emergencies

Interventions

Interventions for specific medical emergencies, such as cardiac arrest (i.e., defibrillation, intubation, IV and medication administration), may be effectively performed while on the scene or prior to hospital transport. Alternatively, it is widely accepted that most interventions for traumatic injuries should be performed while en route to the hospital, and all efforts should be extended to reduce on-scene time.

The issue of IV fluid administration has gained controversy over the past several years. High-volume IV fluid for hemodynamic instability resulting from traumatic injury has traditionally been the accepted standard in most out-of-hospital care systems. Recent data, however, support a paradigm shift to restrictive or hypotensive resuscitation for penetrating truncal injuries. Restoration of hemodynamic stability with fluid resuscitation prior to definitive surgical hemostasis may lead to increased morbidity. Likewise, the use of the pneumatic antishock garment has been shown to increase mortality rates in penetrating torso injuries and is no longer recommended. Similar to medical patients, definitive airway support by endotracheal intubation may be beneficial for severely injured patients although these benefits of intubation in improving patient outcome have not been clearly delineated. To be successful, paramedics must exhibit the technical skills to rapidly place the endotracheal tube correctly, assess the placement, and move the intubated patient appropriately. In addition, providing the correct minute and tidal volumes is equally important. Overzealous personnel subconsciously delivering hyperventilatory rates may impair cardiac output and cause further tissue damage. Patients sustaining blunt head injury pose special problems that must be expeditiously addressed and resolved. Intubation provides a solid means of providing ventilatory assistance and airway protection, but the procedure and postintubation care may negate these potential benefits.
EMTALA REQUIREMENTS FOR PATIENT TRANSFERS

Complete certification (risks and benefits) of transfer
Informed consent obtained from the patient or family
Appropriate transportation (equipment and personnel) arranged
Treatment and stabilization performed
Acceptance from receiving facility ensured
Appropriate patient care data sent (fax or with patient)

EMTALA, Emergency Medical Treatment and Active Labor Act.

Attempting to intubate head-injured patients may result in dental or soft tissue damage in those patients with clenched teeth, and intracranial pressure may be exacerbated from an intact gag reflex or from subsequent regurgitation. Recent studies on the use of RSI in head-injured patients reveal that patients experience significant hypoxia and bradycardia during the procedure, and outcome is actually worse. Thus, the role of RSI in prehospital airway management in trauma patients is in question, just as it is for medical patients.

INTERFACILITY AND SPECIALIZED TRANSPORTS

Transportation between health care facilities may occur for several reasons including patient preference, unavailable diagnostic or therapeutic resource availability at the transferring facility, or managed care requirements that patients be cared for in predesignated hospitals following stabilization. Hospital corporations engaged in networks or alliances that share resources and services depend on interhospital transport systems to convey patients to allied institutions for specialized tests or procedures. Likewise, critical patients admitted to less specialized facilities may need to be transferred to tertiary care or designated trauma centers. Whereas long-distance transports may be best accomplished by air medical services, regional or local transports should use ground systems. These may be provided by either local EMS resources or those owned and operated by the hospital.

Interfacility transfer of patients that is medically indicated must fall under a set of requirements referred to as the Emergency Medical Treatment and Active Labor Act (EMTALA). Although the EMS system providing the transport plays a key role, these guidelines primarily involve particular information and obligations that must be satisfied by the transferring and receiving facility prior to transfer. It is important to note that an unstable patient should not be transferred to another facility at the request of a managed care organization unless the transferring hospital is capable of providing standard care and the receiving hospital does have the capability to manage the condition and foreseeable complications. Box 190-1 lists various requirements that must be completed prior to transferring a patient to another facility.

Depending on patient condition, specialized transport services may function at the BLS or ALS level, providing emergency or nonemergency transportation. Patient transfers considered ALS may include interhospital (either ED or intensive care unit) neonatal or high-risk infant, critical cardiac, or trauma transports. Personnel configuration depends on system design and level of care provided. Many programs use a nurse-paramedic combination. Patients requiring specialized care may need the services of specifically trained individuals, such as respiratory therapists, neonatal nurses, or other specialized critical care personnel. The presence of a physician is not mandatory but may be useful in selected cases.

As with any EMS activity, all interfacility transports should be reviewed for appropriateness of transfer and medical care provided. In 1993, The Practice Management Committee of ACEP updated the 1990 policy statement on interfacility transfers.

THE FUTURE

Providing quality, efficient, and responsible health care to the right patient, in the right setting, at the right time will always be laudable objectives for any system, but there is a need for research to demonstrate which interventions are conducive to better patient outcome. As the call volumes increase, it is imperative that systems focus on those interventions, from both the training and health care delivery perspectives, that are known to be of benefit. Agencies and organizations involved in EMS development and oversight are listed in Table 190-2.

Acknowledgments

The author wishes to express thanks to Joey, Alex, and Marty for the release time required to complete this chapter.

PERSPECTIVE

The history of air medical transport (AMT) dates back to World War I. The French Air Services evacuated soldiers from Serbia using fixed-wing aircraft (airplanes) as ambulances as early as 1915. The first recorded use of a U.S. military air ambulance was in 1918 when an airplane was converted to accommodate a patient in a semirecumbent litter in the rear cockpit. In 1926, the United States Army Air Corps was formed and flew injured troops more than 150 miles from Nicaragua to a hospital in Panama. In World War II, more than 1.1 million sick and wounded soldiers were airlifted to the United States during the last 3 years of the war. The Korean War introduced the rotor-wing aircraft (helicopter) to AMT. In August 1950, a Bell 47 flew the first of more than 20,000 medical evacuations in Korea. Wounded servicemen were strapped to litters outside the aircraft and transported from battalion aid stations to waiting hospital units. During the Vietnam War, Operation Dustoff transported nearly 1 million injured patients to hospitals.

The impact of AMT on the wounded soldier can be shown by comparing time to definitive care and mortality. During World War II, the average time from injury to definitive care was 6 to 12 hours, with a mortality rate of 5.8%. In Korea, the time was 2 to 4 hours, with 2.4% mortality. In Vietnam, the time was 65 minutes, and mortality was less than 1%. Encouraged by the military experience, civilian AMT in the United States was propelled by the 1969 start of the first hospital-sponsored, fixed-wing air medical program. The first civilian helicopter emergency medical services (HEMS) program in the United States was established in 1972.

AVIATION PHYSIOLOGY

A working knowledge of aviation physiology is vital to understanding the effects of AMT on pilots, medical personnel, and patients.

Boyle’s Law

The cornerstone of aviation physiology is Boyle’s law, which states that the volume of a unit of gas (a specified number of molecules) is inversely proportional to the pressure on it. In concrete terms, Boyle’s law means that as altitude increases (and atmospheric pressure decreases), the molecules of gas grow apart, and the volume of the gas expands. With descent (increasing atmospheric pressure), the molecules are condensed, and gas volume contracts.

Physiologic difficulties from expansion and contraction of gases within the closed spaces of the body may occur with any change in altitude. Squeeze injuries occur on descent and are common causes of barotitis and barosinusitis. Air trapped within the sinuses or middle ear cavities cannot be equalized with ambient pressure, and the air within the space contracts, pulling mucosal and neurovascular elements with it. Reverse squeeze injuries occur on ascent. The decrease in barometric pressure leads to an increased volume of the air trapped within the space, exerting pressure on adjacent bony, neurovascular, or parenchymal structures. Ascent injuries can also include barotitis media, barosinusitis, conversion of a simple pneumothorax into a tension pneumothorax, and rupture of a hollow viscus by expansion of intestinal gas. The operation of medical equipment containing closed air space can also be affected. Intrapulmonary flow rates, the pressure in air splints and in pneumatic antishock garment suits, and endotracheal tube cuff volumes may be altered with altitude.

Charles’ Law

Charles’ law follows from the volume effects of Boyle’s law. Charles’ law notes that as the temperature on a volume of gas rises, the volume of the gas also increases. The molecular dispersion seen with increases in gas volume at altitude (Boyle’s law) means there is less chance of molecular collision with resulting generation of heat. Charles’ law explains why the ambient temperature decreases with increased altitude.

Dalton’s Law

Dalton’s law states that the total barometric pressure at any given altitude equals the sum of the partial pressures of gases in the mixture \( P = P_1 + P_2 + P_3 + \ldots + P_n \). As pressure is reduced, expansion of gases creates increasing distances between molecules, and the quantity of oxygen available for respiration decreases. Although oxygen still constitutes 21% of the atmospheric pressure, each breath brings fewer oxygen molecules to the lungs, and hypoxia results (Table 191-1). The clinical effect of Dalton’s law is manifested as a decrease in partial arterial oxygen tension with increasing altitude.

The most threatening feature of hypoxia is its insidious onset. Physiologic responses include an increased rate and depth of respirations and an increase in heart rate. With prolonged exposure, oxygen supply to the brain is insufficient to support cerebral metabolism. Signs and symptoms of cerebral

Po2, partial pressure of alveolar oxygen; PACO2, partial pressure of arterial carbon dioxide.

Hypoxia include headache, nausea, drowsiness, fatigue, and, finally, unconsciousness and death. Although the onset and severity of symptoms may vary with individuals, no one is exempt from the effects of hypoxia, including patients and air medical flight crew.

**Henry’s Law**

Henry’s law states that the mass of gas absorbed by a liquid is directly proportional to the partial pressure of the gas above the liquid. Henry’s law has its most familiar applications in diving medicine, in which the increased pressure exerted on gases in the body at depth forces the gases into solution in the bloodstream. Rapid ascent from depth causes the gas to come out of solution within the bloodstream, resulting in decompression sickness or dysbarism. Henry’s law does not carry the same weight in aviation medicine because the degree of change in atmospheric pressure per unit of distance is considerably less than the degree of change in water. Sudden decompression at high altitude similarly may result in dysbarism, however.

**Additional Stresses of Flight**

Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration. Temperature changes may produce increases in metabolic rate and oxygen consumption. Prolonged exposure can result in motion sickness, disorientation, fatigue, and impaired performance.

As altitude increases and the air cools, the amount of moisture in the air decreases significantly. To prevent dehydration during AMT, fluid intake (oral or intravenous) must be monitored carefully, and all patients should receive humidified medical oxygen. Noise and vibration may represent the most ubiquitous stresses encountered in AMT; both may interfere with patient assessment or the function of medical equipment. Long-term exposure may result in fatigue, nausea, visual or vestibular disturbances, ear damage, and deterioration in task performance. Hearing protection should be worn during aircraft operations by the patient and crew.

**PRINCIPLES OF AIR MEDICAL TRANSPORT SYSTEMS**

**Administrative Structure**

Air medical services may take several forms. Despite a tremendous growth of independent (private) operations in the United States in recent years, the most common type of helicopter service remains the hospital-sponsored operation transporting patients from outlying referral centers or accident scenes to tertiary care centers. A single hospital or a consortium of institutions may sponsor these flight programs. In 2008, there were approximately 219 dedicated HEMS programs operating 668 helicopters—twice as many aircraft as there were in 1998. Single hospitals or consortiums accounted for 71% of the programs but only 50% of the helicopters; the remaining 50% of the helicopters were operated as independent (private) operations.3 Public service agencies may also sponsor air medical services. Vehicles used by these programs are often multifunctional aircraft that serve in medical, search and rescue, fire suppression, and law enforcement roles. The Military Assistance to Safety and Traffic (MAST) program operated by the U.S. Armed Forces may transport ill or injured patients when no civilian service is available and when MAST aircraft, equipment, and personnel are not being used for the unit’s primary military mission. Funded by tax dollars, these programs are often operated at no cost to the patient. In the United States, public-use and MAST helicopters account for more than 160 additional helicopters available for patient transport.3

There is no accurate accounting of the number of fixed-wing air ambulances companies or airplanes. Although some hospitals do sponsor fixed-wing AMT, it is more common for these programs to be private fee-for-service operations.

**Types of Missions**

Air medical missions may involve primary or secondary response. Primary responses (“scene flights”) are responses in which the aircraft serves as the sole means of patient transport to a receiving facility. Aircraft involved in secondary responses—interfacility transport—move patients from outlying hospitals to facilities offering higher levels of care.

AMT missions may also be classified according to the level of care provided. This may include critical care transport, advanced life support, specialty care transport, or basic life support.

**Air Medical Aircraft**

Although the ground ambulance remains the primary means of out-of-hospital and interfacility patient transport, the use of the air ambulance has grown significantly since the 1970s. No one aircraft is ideal for the needs of all air medical programs or for all patients. The vehicle selected should meet the mission requirements of the program for the types of patients to be transported and the anticipated service area.

**Helicopters (Rotor-Wing Aircraft)**

The helicopter offers several advantages over other transport vehicles. Traveling “as the crow flies” at speeds of 120 to 180 mph, helicopter transport time is often 75% less than that
for an equivalent distance by ground transport. The service area of helicopter programs is generally up to 150 to 200 miles from its base of operations. The rotor-wing aircraft has the ability to avoid common traffic delays and ground obstacles and can fly into locations that may be inaccessible to other modes of travel. Helicopter landing zone requirements are a disadvantage compared with ground ambulances but offer an advantage over the airport requirements of airplanes.

Disadvantages to rotor-wing flight include the presence of noise and turbulence, which may interfere with patient evaluation, monitoring, and management. Weather considerations may significantly limit the availability of helicopter transport. In small and medium-sized helicopters, cramped patient compartments and weight limitations (compared to ground ambulances) may limit the number of transport personnel or equipment that can be carried. Occasionally, this may compromise optimal patient care in the transport environment (Fig. 191-1).

Many helicopter programs permit flight only under visual flight rules. When the weather conditions (ceiling and visibility) fall below established program minimums, a program may decline to undertake a transport for safety reasons. However, an increasing number of programs are equipping their helicopters and training their pilots for instrument flight rules (IFR) to allow safe travel in less favorable weather conditions. With the aid of new technology, HEMS programs and hospitals are working together in many areas of the country to develop IFR approaches to private-use hospital helipads. IFR flight does not facilitate travel to the scene of an accident or to hospitals that are not equipped for an instrument approach.

Airplanes (Fixed-Wing Aircraft)

Although rotor-wing missions attract more media attention, fixed-wing flights constitute a significant portion of AMT operations. Fixed-wing aircraft provide increased range; greater speed; and often more patient, crew, and equipment capacity than do rotor-wing vehicles. Decreased cabin noise and turbulence create fewer patient management problems, and pressurization can combat the impact of physiologic gas laws. Fixed-wing operations are limited, however, to areas that have airports, runways of appropriate length or condition, and refueling facilities. During fixed-wing transports, patient transfers require multiple vehicles (i.e., hospital to ground ambulance to airplane).

Various fixed-wing aircraft are available for medical transport. These range from unpressurized light planes with single- or twin-piston engines to pressurized turboprops and jets. The selection of the ideal aircraft depends on the nature of the air medical mission.

Air Medical Flight Crew

Air medical crew members represent the broad spectrum of health care providers. AMT services that provide critical care transport, advanced life support, or specialty care transport must staff the vehicle with a minimum of two medical personnel to provide direct patient care. Most AMT programs in the United States provide critical care transport teams composed of one registered nurse (RN) and an additional crew member. Some fixed-wing AMT services provide basic life support staff with a minimum of one certified/licensed emergency medical technician-basic (EMT-B).

For some AMT programs, crew configuration may be dependent on the mission (adult, pediatric, neonatal, or obstetrics). Data compiled from 1984 to 2005 show that the RN/paramedic team is most often used (>60%) in helicopter and airplane transports. Other combinations, including RN/RN (8%), RN/EMT, RN/physician, RN/respiratory therapist, and EMT-paramedic/EMT-paramedic, account for less than 5% each.

Flight nurses generally have extensive experience in intensive care units or emergency departments. They may be specialized within the transport team to care for adult, pediatric, or neonatal patients. Paramedics often make their greatest contribution in the transport of critically injured patients from the scene of illness or injury. Respiratory therapists bring expertise in airway and ventilator management and oxygen delivery systems. Flight physicians may be residents, attending physicians, or medical directors of flight programs. Early research focused on the specific benefit of the onboard physician. Although the answer to this question remains controversial, it is clear that the crew used by an AMT program must be explicitly tailored to the needs of the community and the patients it serves.

The AMT environment imposes unique considerations on the air medical flight crew that can influence their ability to provide patient care. Human factors work has shown that most medical care procedures are more difficult to perform in an AMT vehicle than in other ground-based settings. Auscultation of the lungs, palpation of pulses, performance of cardiopulmonary resuscitation, endotracheal intubation, and recognition of visual alarms are all impaired while aloft. In addition, fatigue, motion sickness, an erratic pattern of work activity, and the high risk involved in AMT operations may affect task performance significantly.

Medical Direction

All air medical services require the active involvement of a physician as air medical director, who is responsible for supervising, evaluating, and ensuring the quality of medical care provided by the AMT team. Emergency physicians play a significant role, with nearly 50% of all air medical directors having a background in emergency medicine. The air medical director must have the final authority over all clinical aspects of the air medical service. The medical director should ensure that the medical personnel have adequate training and qualifications to deliver appropriate medical care, that appropriate medical equipment and supplies are available, and that the correct vehicle is selected for transport. Medical care policies and procedures should be established, including specific pro-
visions for online and offline medical control. The Air Medical Physician Association and the National Association of EMS Physicians have established guidelines for the medical director of an air medical service.  

### Safety

Safety is the predominant concern of air medical operations, and ensuring safe conduct is a fundamental part of every flight program. Safety must also be an overriding consideration of medical and public safety personnel when considering the risks and benefits of AMT for every patient being transferred. Continual training of aircraft pilots and mechanics is essential, and both participate in ensuring the airworthiness of the vehicle. Medical personnel must be proficient in the emergency operations of the aircraft and the routine procedures in and around their helicopter or airplane. Crew fatigue and other self-imposed stresses that could affect safety, such as the use of prescription or over-the-counter medications, tobacco, and alcohol, must be scrupulously avoided.

Weather requirements or “minimums” must be strictly enforced. On receipt of a flight request, the pilot must verify the weather conditions and the condition of the aircraft. To ensure impartiality, the pilot should not be told of the patient’s condition or acuity. The pilot always has the right to decline a mission because of aircraft or weather considerations. These decisions must not be influenced or reversed by administrators, flight crew, or other parties.

A practice that should be avoided with regard to helicopter transport and poor weather conditions is “helicopter shopping.” The Federal Aviation Administration (FAA) has found that this dangerous operational practice has been a factor in several fatal HEMS accidents. *Helicopter shopping* refers to the practice of a requesting EMS agency or hospital calling numerous HEMS operators until one agrees to accept a flight—without disclosing with the accepting HEMS operator that other programs have declined the flight due to bad weather. Although there may be circumstances in which a subsequent program can safely undertake and complete the flight, helicopter shopping can lead to an unsafe situation in which a program initiates a flight that it would have declined if it had been aware of all of the facts surrounding the request. In 2006, the FAA issued a letter to all state EMS directors describing helicopter shopping and requesting that they take action to prohibit this practice.

### Landing Zones

Helicopter landing zones are inherently dangerous places. The most obvious risk of injury is from impact with rotor blades. This danger is heightened during ground operations because the blades dip lowest to the ground at the slower rotor speeds associated with engine start-up and shutdown. Injuries also may occur as a result of debris being propelled through the air by “rotor wash,” increased noise levels and an inability to hear warnings, and slippery surfaces found on exposed landing sites.

Many hospitals have designated landing areas that are appropriately lit and secured (Fig. 191-2), with fixed coordinates and predesignated liftoff and approach patterns. Most primary responses occur at unmarked sites, however. Ground personnel must be trained to designate and secure a safe landing zone for helicopter operations (Box 191-1). AMT programs have an obligation to help train ground staff on proper landing zone setup and conduct (Box 191-2).

Helicopter flights direct to the scene of an accident pose a unique risk to AMT due to potential hazards near the landing zone. This is especially true at night. In response to this, some out-of-hospital care providers and flight programs have found it beneficial and safer to utilize a rural or community hospital helipad to rendezvous. For some hospitals and emergency physicians, this has raised concerns regarding Emergency Medical Treatment and Active Labor Act (EMTALA) responsibilities to provide a medical screening exam for these patients. In May 2004, the Centers for Medicare and Medicaid Services (CMS) resolved this concern; CMS stated that the use of a helipad on hospital property that has a dedicated emergency department does not trigger EMTALA as long as the helipad is being used as a helistop for EMS personnel to rendezvous with air medical transport to complete the transport of a patient to a tertiary care or the closest appropriate facility.

Another adjunct to landing zone safety and night operations in general is the increasing utilization of Night Vision Goggles (NVG). A growing number of AMT programs are equipping their aircraft with NVGs and training their pilots and medical crews to use this sophisticated technology. NVGs dramatically magnify ambient light from the moon or stars to illuminate the ground, as well as natural terrain and man-made obstacles that could interfere with safe flight or landing.

### Integration of AMT within Emergency Medical Service Systems

AMT should be an integral resource within a comprehensive EMS system. Integration begins with the establishment of geographic service areas. Service areas may be determined based on program mission description, aircraft range and speed, the placement of specialty centers and receiving facilities, and the location and mission of air medical programs in adjacent regions. Population densities are also key factors. Helicopters are generally less useful in urban settings because of the proximity of health care facilities and a lack of open and safe landing zones. Paramedics, EMTs, and other public safety personnel should be provided with guidelines specifying when AMT should be considered. These protocols are best developed by EMS medical directors in close collaboration with their air medical colleagues.

### CLINICAL CONCEPTS AND PATIENT CARE

Although virtually all types of patients have been transported by air medical services, definitive prospective data indicating which patients will benefit from flight are lacking. Many ques-
Chapter 191 / Air Medical Transport

**SAFETY OF PERSONNEL APPROACHING AND DISEMBARKING A HELICOPTER**

- Vehicles and personnel should be kept at least 100 ft from the landing zone.
- Spectators should be kept at least 200 ft from the landing zone.
- No smoking or running is permitted within 50 ft of the helicopter.
- All items (e.g., IV lines, poles) should be kept below shoulder height.
- The flight crew opens and closes aircraft doors.
- The flight crew directs and supervises the loading and unloading of the patient and equipment.
- Ground personnel should use eye and ear protection.
- Approach the helicopter only when signaled to do so by the pilot or an onboard crew member.
- Approach and depart the helicopter only forward of the rear cabin door and in a crouched position with your head down.
- Never approach or depart from the rear of the helicopter.
- Stay clear of the tail rotor; it is virtually invisible and extremely dangerous.
- If the aircraft is parked on a slope, approach and depart on the downhill side (greatest clearance under the blades).
- Keep the landing zone clear of (or hold on to) all loose articles (e.g., hats, scarves, sheets, pillows).
- Protect patient from the dust and debris.
- Follow the flight crew’s instructions at all times.
- In disaster situations and mass casualty incidents, victims, witnesses, and spectators may become hysterical or exhibit signs of an acute situational reaction. These individuals must be kept clear of the landing zone and helicopter at all times. Injured victims who exhibit this behavior should not be triaged for helicopter transport, or they should be transported only with adequate physical or chemical restraints in use.

*If you do not know, ask.*

---

**LANDING ZONE (LZ) REQUIREMENTS FOR AIR MEDICAL TRANSPORT**

**Landing Area**
- LZ should be as close as possible to the scene or hospital entrance, but not so close that it may interfere with ground operations or patient care.
- LZ should be at least 100 x 100 ft.
- LZ should be as flat and level as possible.
- LZ must be clear of debris.

**Hazards and Obstructions**
- Identify all potential hazards that may be on the ground or near the approach/departure path of LZ.
- LZ should be clear of wires, poles, trees, buildings, vehicles, and spectators.
- Road cones, ropes, tape, and barricades are not recommended for use near LZ.
- Perimeter of LZ should be at least 50 ft away from potential obstructions and hazards.
- LZ should be located upwind from any hazardous material incident.

**Approach and Departure Path**
- Path should point into the wind and be free of obstruction to an altitude of 500 ft above the surface.
- Path should not pass over command posts, treatment areas, or operationally congested areas on the ground.

**Day Operations**
- Use radio communications and hand signals.
- Stand with your back to the wind.

**Night Operations**
- Use radio communications and lighting to designate LZ.
- Spotlight should be directed at the top of possible hazards, not toward the approaching or departing aircraft.
- Position a portable light, vehicle headlights, emergency vehicle flashing lights, flare, or chemical stick at each corner, with a fifth light upwind.
- Nonessential lights should be turned off.

**Light Sources**
- Lights must be clear of LZ.
- If portable, lights must be well secured.
- Never point lights toward an approaching or departing helicopter.

**Wind Indicator**
- Indicator may be a wind sock, flag, flare, or smoke.
- Indicator must be clear of LZ.
- If portable, indicator must be well secured.

*Courtesy of University of Chicago Aeromedical Network (UCAN), University of Chicago Medical Center, and Illinois Association of Air and Critical Care Transport (IAACCT), 2008.*
ctions regarding the triage of patients to air or ground transport, the efficacy of air medical care, and the effects of AMT on morbidity and mortality in medical and surgical conditions remain unanswered. In an effort to ensure that AMT resources are used wisely, the Air Medical Physician Association has established a detailed medical condition list for the appropriate use of AMT.26 A more general approach to the need for AMT is illustrated in Box 191-3.

**Trauma**

Although there are some analyses of HEMS use for secondary (interfacility) missions, the vast majority of trauma studies have addressed air medical utilization for scene response.27–29 There are data from Pennsylvania and California brain-injured patients undergoing out-of-hospital intubation demonstrating HEMS-associated improvements in both morbidity and mortality in patients with traumatic brain injury.30,31

Methodologic heterogeneity precludes formal meta-analysis of the AMT outcomes data. However, in considering the mortality benefit that appears to be associated with HEMS, existing data support an estimate of 20 to 35% survival improvement, or the saving of three to six lives (perhaps fewer for pediatric patients) per 100 air medical trauma flights.32–39 Furthermore, trauma systems experts’ finding that HEMS represents the only modality by which nearly 28% of U.S. residents have timely (i.e., within 1 hour) access to level I or II trauma centers emphasizes the vital role of AMT in care of the injured patient.40 Studies have also presented data that suggest lack of HEMS benefit, but these studies are a small minority and are limited by confounding and methodologic quirks such as inclusion of a preponderance of transports to nontrauma centers.41,42

On the other hand, seminal work in HEMS casts doubt on the supposed logistical advantages of helicopter dispatch.43 Faster times to trauma centers are not required for air medical accrual of outcomes benefit. Studies conducted from regions as disparate as California and The Netherlands demonstrate HEMS mortality benefit but find similar scene-to-trauma center times for ground and air transports.39,44 Even so, it seems clear that for many patients, factors other than speed are responsible for AMT’s benefits.

AMT is unlikely to improve outcome in those whose injuries are either trivial or grave. For instance, if the Injury Severity Score’s 75-point scale is collapsed into five ordinal categories, analysis finds a significant association between helicopter transport and improved mortality in the middle three categories (survival odds ratios range from 2.1 to 2.6).45,46

**Cardiac Disorders**

The ability to study HEMS-related outcomes benefit in acute coronary syndrome is limited by the lack of validated scores that can be used to stratify risk and predict outcome. There are data demonstrating the use of helicopter transport to extend the ability of primary angioplasty centers, with outcomes of patients flown from a distance equaling outcomes of patients presenting primarily to the cardiac referral center.47,48

Although HEMS could conceivably shorten door to percutaneous coronary intervention (PCI) time by transporting patients rapidly from hospitals without PCI capability to a referral center, in some circumstances the patient will be best served by receiving thrombolytic therapy in the sending hospital and then being transported by the most appropriate mode of transport (air or ground ambulance). In other situations, however, pre-hospital and interfacility helicopter transport can play an important contributory role in extending regional cardiac care systems and primary PCI to many patients.

**Stroke**

With the advent of time-critical therapy for ischemic stroke, HEMS has played an increasing role in the regionalization of acute neurologic care. Early studies demonstrating safety of transport of post-thrombolysis stroke patients have been complemented by case series illustrating the increasing use of helicopter interfacility transport for stroke.49,50 However, once a patient has received thrombolysis, the risk-benefit analysis for air versus ground transport may be altered. For many patients, ground ambulance transport will be appropriate. For other patients, however, the referring physician may determine that AMT is still warranted. Case reports and series have demonstrated the utility of air medical dispatch for primary (scene) transport of patients with strong suspicion of stroke.51–53

In one region, ground EMS providers were able to identify stroke with accuracy (nearly four out of five air-transported patients had the diagnosis confirmed), and helicopter-transported patients comprised nearly one fourth of the stroke center’s thrombolysis volume.52 The use of strict triage definitions keeps inappropriate calls for AMT to acceptably low levels while allowing for a significant extension of the geography served by an individual stroke center.52

---

**Box 191-3**

**Criteria for Air Medical Transport (AMT)**

1. Distance to the closest appropriate facility is too great for safe and timely transport by ground ambulance.
2. Patient’s clinical condition requires that the transport be short as possible.
3. Patient’s condition is critical, requiring specific or timely treatment not available at the referring hospital.
4. Potential for transport delay associated with ground transport is likely to worsen the patient’s clinical condition.
5. Patient requires critical care life support during transport that was not available from the local ground ambulance service.
6. Patient is located in an area inaccessible to regular ground traffic, impeding ambulance egress or access.
7. Local ground units are not available for long-distance transport.
8. Use of local ground transport services would leave the local area without adequate EMS coverage.
9. For interfacility medical transport, the requesting physician based on his/her best medical judgment and information available at that time of transport determined the need for AMT.
10. For scene medical transport, the requesting authorized out-of-hospital provider based on applicable policy, his/her best medical judgment and information available at that time of transport determined the need for AMT.

Neonates and Children

The use of AMT to extend the reach of neonatal care centers is reported from many settings. The most rigorous analysis suggests that long-distance AMT allows for infants from remote areas to achieve outcomes as good as those achieved with infants born in urban centers. Although neonates are vulnerable to physiologic deterioration, air transport is associated with no more derangement in oxygenation and ventilation than is transport (with the same team) by ground vehicle.

Many areas depend on AMT to deliver critically ill or injured children to regional pediatric centers. Although speed of transport may be an important consideration, the emphasis is often more on the transport team than on the mode of transport. Experienced pediatric transfer teams often bring a level of expertise unavailable to the pediatric patient in the outlying hospital. Appropriate training, experience, and competency are essential for those responsible for the transport of critically ill or injured children. Depending on regional AMT and pediatric resources, the transport team may be a regularly scheduled transport team or a pediatric specialty team. Several studies have compared pediatric transports conducted by specialty pediatric teams versus regularly scheduled transport teams. Specialized pediatric transport teams, including services providing extracorporeal membrane oxygenation, were found to have comparable outcomes and fewer adverse events.

Efficacy and Cost-Effectiveness

Cost-benefit is deservedly an area of increasing focus for AMT. Part of the problem lies in the imperfections of current triage (e.g., for trauma) and the inability to precisely identify, in prospective manner, which patients will truly benefit from helicopter EMS. However, it is equally true that in some regions there is little, if any, guidance regarding when air medical dispatch is indicated. Using endorsed guidelines for air medical dispatch, EMS regional authorities should collaborate to generate criteria best for their own systems, with constant refinement as indicated by rigorous utilization review.

Fortunately, compared to the cost-benefit ratios of widely accepted medical interventions, AMT is well within the accepted range per quality-adjusted life-year saved. One Scandinavian study, with a large proportion of rural transports, concluded, “The analysis indicates that the benefits of ambulance missions flown by helicopters exceeds the costs by a factor of almost six.” Another group from the region estimates that HEMS contributes to the cost-effectiveness of primary PCI; even when patients were transported from longer distances (and by air), the cost-effectiveness of primary PCI over time is maintained. Other investigators have demonstrated the favorable cost-effectiveness of helicopter stroke transports.

Cost-effectiveness determinations are not straightforward. It is difficult to calculate true cost-effectiveness for helicopter use for transports that would otherwise not occur (as with high-risk obstetrics cases) or would deliver patients outside critical time windows (as for stroke or cardiac transports). There is no ground transport option capable of rapidly moving through rush hour traffic in Los Angeles or getting patients from coastal islands to neurointerventional or cardiac catheterization suites. Because HEMS represents the only mechanism by which more than 80 million U.S. citizens have timely access to mortality-improving high-level trauma center care, it is obvious that some form of air transport is a “must-have” for some U.S. EMS regions. The direct bearing on the cost-effectiveness calculations is not difficult to understand: If a region must have air medical assets for some group, then it is most reasonable to amortize the “overhead” costs across all transported patients.

Also, air transport costs should be compared with those of the real-life alternative mode of transport. In many cases, AMT is arguably less expensive than the alternative. Unfortunately, the job of assessing HEMS’ cost-effectiveness is rendered difficult by the extremely limited amount of information on cost-effectiveness of ground EMS. Crew and patient safety are issues in both air and ground systems.

Future of Air Medical Transport

AMT faces many challenges. The dramatic increase in the number of medical helicopters in the United States since the late 1990s has heightened concerns for their inappropriate use. AMT services work best when they are integral to and enhance an overall system of out-of-hospital care and interfacility transport. Systems must be in place to educate requesting agencies and professionals regarding the appropriate use of available air and ground resources. At the same time, flight programs must be more vigilant in terms of triage. It also seems that advances in ground-based EMS and the availability of critical care ground ambulances for interfacility transports are offsetting many of the assumed benefits of AMT. However, geographic issues, the regionalization of specialty services, the development of new highly time-sensitive therapies, and the need to transport patients quickly over long distances will require that there be systems in place to continually assess the potential value of initiating or continuing AMT.

Research into these issues is a key facet of the future of AMT. The challenge with HEMS and outcomes research is not whether but, rather, in whom there is benefit. Currently, the major dilemma facing helicopter transport outcomes researchers is the identification of triage variables that can prospectively (i.e., at the time of transport vehicle selection) guide utilization of the air medical resource.

Safety must be the priority in AMT. AMT programs, aviation operators, air medical associations, and regulatory agencies continue to address this issue. However, it is important to remember the significant role that requesting and receiving personnel can also play with regard to AMT safety and the safe transport of their patients.

TACTICAL EMERGENCY MEDICAL SUPPORT (TEMS)

Perspective

Law enforcement agencies in the 21st century face an increase in terrorist threats and new challenges, including organized opposing forces, military-type weapons, direct fire, hostage and barricade situations, and potential toxic hazards. As these threats have increased, so has the recognition of the need for integrated medical support of tactical operations.1,2 Tactical emergency medical support (TEMS) is the specialty of emergency medical services (EMS) established to maintain safety, health, and welfare for combat medical units and special operations civilian law enforcement units, such as special weapons and tactics (SWAT) teams, hostage rescue teams, and special emergency rescue teams.2,4 These specially trained teams are composed of highly trained and specially equipped personnel who are tasked with mitigating and responding to many different high-risk situations.2,4 Events such as the World Trade Center bombings and hurricane Katrina have demonstrated the need for many nonhospital health care personnel to use some of these current military out-of-hospital medical strategies.

Tactical Medical History

The principles of TEMS have largely been developed through lessons learned from military conflicts. Civilian TEMS structure most closely emulates the medical support structure of military special operations units such as Army Special Forces, Navy Seals, Army Rangers, and Air Force Pararescuemen.2,5 These small, unique tactical units frequently operate outside the normal realm of military operations remote from dedicated medical resources, often for long periods of time.

In the civilian setting, snipers, mass demonstrations, riots, and fire bombings gained notoriety as new forms of urban conflict in the United States during the late 1960s and early 1970s, which led to the formation of the first SWAT unit. In 1996, there were more than 5000 SWAT teams in the United States supporting local, state, and federal agencies.9 Essentially today, more than 90% of municipalities with a population greater than 50,000 have a SWAT team. With the evolution of these specialized law enforcement tactical teams, the need for military-style EMS support began to emerge.

Due to the dangerous environment, SWAT team members are at high risk for injury, with a casualty rate of 33 injuries per 1000 officer missions.1 Suspects are injured at the rate of 18.9 injuries per 1000 officer missions and bystanders are injured at the rate of 3.2 per 1000 officer missions. It was recognized that traditional EMS providers were not properly trained or equipped to enter these unique and sometimes remote austere environments to care for casualties.1,2,10,11 In fact, basic EMS training still emphasizes that personnel should wait until the “scene is safe” before rendering medical care to patients. Past incidents such as shootings at Columbine High School in Littleton, Colorado, Ruby Ridge in Idaho, the University of Texas in Austin, and the Mormon Library in Salt Lake City proved that sequestering medical personnel far from the area of operations leads to delays in definitive trauma care, with potentially higher morbidity and mortality.10-13 The tactical environment necessitates the medical provider possess a unique training and skill subset to utilize a different set of field assessment and treatment priorities and strategies for monitoring and sustaining health maintenance. Provision of tactical medical care has now become an integral part of preplanning for federal, state, and local tactical teams in response from lessons learned.2,5

The inadequacy of the previously discussed civilian trauma model for application in tactical situations was expounded upon by Butler and Hagmann in their landmark 1996 paper.11 Since this publication, the principles of “tactical combat casualty care” (TCCC) have been refined and now applied on today’s battlefield11 as well as in most civilian TEMS teams.20,21 TCCC is a set of principles that aim to prevent further casualties, accomplish the tactical mission, save the maximum number of lives, and minimize morbidity of the injured. The TCCC guidelines are based on treating the leading preventable causes of battlefield death, which include hemorrhage from a compressible site, tension pneumothorax, and airway compromise.22,23 In the most recent TCCC guidelines, attention to hypothermia prevention, intravenous access, improved en route care, and pain management techniques are also addressed.20

Goals of Tactical Emergency Medical Support

In the early years, TEMS role was for care and evacuation of wounded. This role has evolved with more emphasis on mission planning, primary care, preventive medicine, and emergency care of illness and injury. Although the primary goal of TEMS is to enhance the law enforcement mission, the tactical medical role involves a continuum of care that includes maintenance of team health; reconnaissance of environmental and situational aspects of the mission;
Goals

Deployed in support of law enforcement operations.

Developed one such surgical resuscitation team that has been functional in remote areas. The Medical College of Georgia has shown teams similar to military forward surgical teams that can function, and also require tactical training. In addition, there is a growing need for forward surgical teams overseas there is a growing need for forward surgical teams to be able to support the assault team. There are also rescue teams, backup teams, and hostage and negotiation teams. A unit commander supervises the operation from a command post.

The TEMS component of a tactical unit, like team structure, varies widely throughout the United States. Some SWAT teams use “standby” EMS personnel, whereas others have physician-only TEMS providers. Much like the military Special Forces, many civilian tactical law enforcement agencies are now integrating medical support into the tactical team in order to enhance mission success.

Although not ideal, the minimal medical coverage at a tactical location should be the use of standby civilian EMS personnel in a predetermined location. The standby EMS personnel treat casualties that are brought to them but are unable to assist in medical preplanning or inner perimeter rescue. This minimal medical support for tactical missions may be inadequate for some missions, given the high degree of potential injury and delay in definitive care.

Law enforcement agencies using integrated medical support have varying medical qualifications. The use of EMT-Bs for medical coverage has the advantage of availability and modest cost. Medical directors may be able to train basic providers with an enhanced skill set in order to provide appropriate medical care for tactical support. However, the increased skill set possessed by advanced nonhospital providers makes them favorable in a TEMS environment. In a small number of jurisdictions, emergency physicians and residents provide medical oversight for TEMS units and are also deployed as medical operators in the tactical environment. Although physician providers offer a broader scope of practice and do not require direct medical control, they usually have limited out-of-hospital experience and also require tactical training. In addition, as the law enforcement mission takes on additional roles overseas there is a growing need for forward surgical teams similar to military forward surgical teams that can function in remote areas. The Medical College of Georgia has developed one such surgical resuscitation team that has been deployed in support of law enforcement operations.

Table 192-1  Goals of Tactical Emergency Medical Support

<table>
<thead>
<tr>
<th>Goal</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Enhance mission accomplishment</td>
<td>Ensure that the mission is successfully completed</td>
</tr>
<tr>
<td>Prepare medical threat assessment</td>
<td>Develop a plan for potential medical threats</td>
</tr>
<tr>
<td>Monitor the medical effects of environmental conditions</td>
<td>Keep track of the impact of environmental conditions on the medical situation</td>
</tr>
<tr>
<td>Reduce death, injury and illness, and related effects among team members, innocents, and perpetrators</td>
<td>Minimize harm to both the team and civilian population</td>
</tr>
<tr>
<td>Reduce lost work time</td>
<td>Minimize the time lost due to injuries or illness</td>
</tr>
<tr>
<td>Maintain good team morale</td>
<td>Keep the team motivated and functioning effectively</td>
</tr>
<tr>
<td>Maintain health of team and provide preventive medicine</td>
<td>Ensure the health and well-being of the team</td>
</tr>
<tr>
<td>Coordinate with surrounding agencies and hospitals</td>
<td>Effectively communicate with external agencies</td>
</tr>
<tr>
<td>Decrease liability</td>
<td>Minimize legal risk and liability</td>
</tr>
<tr>
<td>Possess basic forensic knowledge and crime scene preservation</td>
<td>Be able to provide forensic knowledge and preserve crime scenes</td>
</tr>
</tbody>
</table>

The tactical environment is different from the traditional EMS environment. Traditional EMS doctrine taught personnel to ensure the scene is “safe” before attempting to render care. This principle is not possible in some tactical situations. Tactical training needs to take into account team tactics and movement; cover and concealment; equipment issues; nuclear, biological, and chemical training; rappelling; weapons familiarity; and noise and light discipline training. Also, routine training needs to be done in basic rescue tactics, tactical room entries, open area rescues and tactics, movement under fire, cover and concealment, officer down drills, and, in some systems, firearm training (Fig. 192-1). Furthermore, many teams are now training all team members on medical management for lifesaving interventions.

In the military and operational environments, there is a significant increase in the number of penetrating traumatic injuries (gunshot, fragmentary, and blast propellant wounds, etc.). Due to the increased complexity and number of combat casualties and the possibility that civilian TEMS providers may be exposed to such, additional training and knowledge of the TCCC guidelines are important for the operational and tactical medic. Although advanced trauma life support may be applicable to the emergency department management of trauma patients in both civilian and military hospitals, it was not created for combat or tactical out-of-hospital
The three goals of TCCC are to (1) treat the casualty, (2) prevent additional casualties, and (3) complete the mission. TCCC is divided into three distinct phases to provide the correct medical interventions at the correct time in the continuum of out-of-hospital care (Table 192-2).

Care under Fire. In terms of medical delivery in the civilian tactical environment, the area is usually divided into three zones—cold, warm, and hot.2,28 These zones are based on tactical environment, threat level, and treatment options, which are based on a risk-benefit ratio relative to the medical provider and patient. The cold zone is a safe environment with no threat to injury. This zone is outside the inner perimeter and regular EMS treatment principles usually apply. In the warm zone, threat is not considered immediate but still exists. Finally, the hot zone is characterized by possible direct exposure to hostile fire.

As such, care under fire refers to care being rendered in the “hot zone.” In this zone, the medical and casualty are under direct effective hostile fire. Care in this phase is very limited but not nonexistent. When care may be rendered, airway management, the first medical priority in routine out-of-hospital medicine, is best deferred until the tactical field care phase due to difficulty maintaining the airway during evacuation under direct fire. Also, cardiopulmonary resuscitation and C-spine immobilization have little or no role in the treatment of threat to injury. This zone is outside the inner perimeter and regular EMS treatment principles usually apply. In the warm zone, threat is not considered immediate but still exists. Finally, the hot zone is characterized by possible direct exposure to hostile fire.

Uncontrolled extremity or otherwise compressible hemorrhage remains the leading cause of preventable battlefield death, and 7 to 9% of all fatalities since the Korean conflict have resulted from wounds potentially amenable to first aid. During the current conflict in Iraq and Afghanistan, newer tourniquets, hemostatic agents, and dressings and intravenous therapies have been developed, researched, and fielded by the military with unprecedented speed. During the “care under fire” phase, hemorrhage control is ideally gained through the use of tourniquets. Although shunned for many years, tourniquets have reemerged as the standard of care in this environment due to low complication rates, ease of use, rapid application, and effectiveness in stopping blood loss. Most tourniquets used previously were improvised with rubber tubing, rifle slings, belts, and so on and not specifically fabricated as they are today. Improvised tourniquets such as rubber surgical tubing are not recommended and should be used with extreme caution. Several case series and reports have found that tourniquet use on the current battlefield has not resulted in increased limb loss or permanent disability even among patients thought to have had tourniquets applied unnecessarily.

Many types of tourniquets are available. The tourniquet in use today’s battlefield by the U.S. Army is the combat action tourniquet, which has received very good reviews from current operators in the field. Based on current literature, both the U.S. and the Israeli military, the International Committee of the Red Cross, and civilian agencies in the United States have embraced tourniquets as an initial hemorrhage control option during a care under fire phase in order to achieve rapid control of bleeding. The current TCCC recommendation is for liberal use of appropriate tourniquets for uncontrolled extremity hemorrhage in the tactical environment.

Tactical Field Care. The second phase of care, tactical field care, is medical treatment rendered in the warm zone. This phase consists of medical care that is delivered while the medic and casualty are still under threat of injury but not under direct, effective hostile fire. Simply by dragging a casualty 5 feet around the corner of a building could transition the medic from care under fire to tactical field care. Care in this phase focuses on several areas that have been shown to increase morbidity and mortality in tactical environments if not addressed. Airway establishment and maintenance is first addressed in this phase of treatment. Next, breathing issues such as tension pneumothorax and open pneumothorax (sucking chest wound) may need to be addressed in this phase of care. Circulatory issues such as tourniquet replacement with direct pressure dressings or advanced hemostatic agents and correct fluid therapy are then addressed. Intravenous (IV) access needs to be established. Hypothermia prevention, adequate analgesia, prophylactic antibiotics, and appropriate use of cardiopulmonary resuscitation are also addressed in this phase.

Advanced Hemostatic Agents. The ideal out-of-hospital hemostatic agent ideally would require little training; be nonperishable, durable, flexible, and inexpensive; adhere to the wound only; pose no direct risk of disease; not induce a tissue reaction; and effectively control hemorrhage from arterial, venous, and soft tissue bleeding. There is no single ideal advanced hemostatic agent that currently meets all of these criteria for either military or civilian use. However, many hemostatic agents have been used successfully for uncontrolled hemorrhage on today’s battlefield and have contributed to reduced morbidity and mortality in penetrating combat trauma.

Three agents are utilized in current military operations: QuikClot (Z-Medica, Wallingford, Conn.), HemCon bandage (HemCon, Tigard, Ore.), and ChitoFlex (HemCon). Newer agents are being fielded.

Intravenous Hemostatic Agents. In the future, optimal out-of-hospital hemorrhagic control in the combat environment may also involve use of IV agents. In selected combat nonhospital settings, appropriate use of factor VIIa and blood products may help reduce coagulopathy and mortality. Also, hemoglobin-based oxygen carrying resuscitative fluids may become available.

Tension Pneumothorax. The second leading cause of potentially preventable battlefield death is tension pneumothorax, accounting for 3 or 4% of all fatal injuries. McPherson and colleagues studied radiologic and autopsy examinations of 978 fatalities from the Vietnam conflict; 15 of the casualties with identified tension pneumothorax lived long enough to be treated by a medic, but none underwent needle decompression and all of them died.

Although needle thoracostomy is a controversial procedure in the civilian trauma setting for adults, current TCCC guidelines recommend consideration of needle decompression in casualties with chest trauma and progressing respiratory distress.

Airway Management. The third leading cause of potentially preventable battlefield death is airway compromise. Although the incidence in the conflicts in Iraq and Afghanistan is unknown and is currently being studied, historically airway compromise is responsible for approximately 1% of fatal injuries on the battlefield. According to Bellamy’s analysis from the Vietnam era, approximately 80% of these injuries are due to facial or neck trauma causing obstruction and compromise of the airway.
Initially, in an unconscious patient with intact upper airway anatomy at risk for airway compromise, the recovery position and minimally invasive adjuncts such as the nasal pharyngeal and the oral pharyngeal airway are emphasized. However, given the high incidence of trauma as a cause of airway obstruction, the cricothyroidotomy is taught as the definitive airway management technique on the battlefield if simple maneuvers fail. Traditional methods providing ventilation, such as endotracheal intubation, the laryngeal mask airway, the combitube, or the King laryngeal tube airway, may not be as feasible in tactical situations. The initial training requirements as well as maintenance issues for these skills for all military medics are simply not practical. Furthermore, use of white light required for laryngoscopy may draw enemy fire on the battlefield. Finally, based on the best available data, many patients needing airway management will likely have disrupted upper airway anatomy, for which these skills would not be successful and cricothyroidotomy would be indicated.

**Intravenous Access and Fluid Resuscitation.** The tactical environment often makes IV access difficult, and alternate techniques and routes may be needed to establish access. Medics therefore are trained to obtain intraosseous (IO) access for fluid administration. Several newer IO devices are utilized in both civilian and combat tactical environments, including the EZ-IO, the Pyng FAST-1 sternal IO, and the Bone Injection Gun.

The current recommendations for IV resuscitation on the battlefield focus only on those patients with signs of hemorrhagic shock. Because the majority of combat casualties present with non-life-threatening penetrating extremity injuries, the number of casualties actually requiring IV fluids in the field is few. TCCC guidelines recommend an infusion of 500 mL of Hextend, followed by an additional 500 mL in 30 minutes if shock is still present.

Hextend, a colloid, is the recommended fluid of choice over crystalloid solutions. Hextend remains in the intravascular space longer, requiring significantly less volume than crystalloids. These factors are critical when supplies must be carried in the medic’s pack. Future battlefield resuscitation strategies may include hypertonic saline, or combinations of hypertonic solutions and colloids. A growing scientific literature supports this “hypotensive resuscitation” strategy.

**Hypothermia Management.** Hypothermia has been well recognized as an independent contributing factor for increased morbidity and mortality in trauma patients. Studies have shown hypothermia to be associated with increases in acidosis, coagulopathy, multiple organ failure, length of hospital stay, and mortality. In the austere environment, prolonged out-of-hospital times, cold fluid administration, and environmental factors affect the patient’s core temperature, as does bleeding that results in hypoperfusion, which alters the body’s thermoregulation and results in hypothermia.

TCCC emphasizes prevention of hypothermia (<34°C) in patients with penetrating trauma. Prevention of heat loss should start as soon as possible after wounding. This is optimally accomplished in a layered manner. Several new devices are being tested and fielded in the combat out-of-hospital setting for hypothermia prevention.

**Analgesia.** The tactical environment exacerbates the typical challenges found in treating acute pain and has the additional obstacles of a lack of supplies and equipment, delayed or prolonged evacuation times and distances, devastating injuries, provider inexperience, and dangerous tactical situations. Studies have shown that failure to recognize and appropriately treat acute pain may result in an increased incidence of chronic pain and post-traumatic stress disorder.

Finally, other newer agents and routes of delivery are being utilized on the battlefield to treat analgesia. Oral transmucosal fentanyl citrate has been found to relieve moderate to severe pain on the battlefield and is currently carried by many Special Forces medics. Also, ketamine has been utilized successfully as an out-of-hospital analgesic in the combat setting. Ketamine in subanesthetic doses is an almost ideal analgesic because of its profound pain relief, its role in preventing opioid hyperalgesia, and its large margin of safety.

**Triage and Advanced Vital Signs.** It has been hypothesized that some trauma deaths may be preventable if the severity of blood loss can be recognized earlier during out-of-hospital medical care.

In an attempt to provide new possibilities for more efficient algorithms that may assist in determination of treatment and evacuation priorities for patients with unrecognized hypovolemia, new and more accurate noninvasive indicators of the underlying physiologic status in trauma patients who have initial normal systolic blood pressure and Glasgow Coma Scale have been investigated and implemented in current combat operations. Some of these indicators of hypovolemia include derived physiologic variables (e.g., shock index, pulse pressure, and field trauma score) and continuous “real-time” variables (e.g., electrocardiogram R wave amplitude and heart rate variability). The National Association of EMS Physicians, with funding from the Centers for Disease Control and Prevention, has led an effort to standardize mass casualty triage. Through this project, a new triage system has been developed that utilizes the principles of TCCC. This system is called Sort Assess Life Saving Triage and has been endorsed by multiple organizations, including the American College of Emergency Physicians.

**Combat Casualty Evacuation Care.** Combat casualty evacuation care is the third phase of care. It is rendered to the casualty in the cold zone and while the casualty is evacuated to definitive medical care. Care now begins to closely approximate traditional civilian field medical care and includes advanced life support en route to the receiving facility, often a trauma center.

Figure 192-2. Combat casualty evacuation care is usually provided via aeromedical transport or advanced life support ambulance in the civilian setting. (Photo courtesy of the Augusta Chronicle and Andrew Davis Tucker.)
TEMSS Environment

Training
Practicing effective medical care in the tactical environment requires TEMS personnel to be well educated, trained, and equipped. Integrated “team” training allows the medical support members to understand their roles and learn all aspects of tactical law enforcement operations and fundamentals on how to approach the tactical medical arena. Unique medical scenario-driven protocols should be developed and rehearsed with the tactical team. These specialized protocols may require advanced practice, and they require medical control approval that should also satisfy state or federal regulations.6,5,6

Equipment
The medical equipment selected and carried by TEMS providers varies and is based on usage, size, weight, budget, training, experience, and mission type. Use of conventional EMS medications and equipment with bright markings and color coding is often discouraged in the tactical environment in order to maintain concealment.

Remote Patient Assessment
Remote patient assessment is another function of TEMS and is done when a person is injured and medical personnel must assess the patient from a distance using binoculars, gun scopes, night vision goggles, cameras, and microwave radar motion detectors.

Hazardous Materials
Incidents involving clandestine drug labs and weapons of mass destruction are also considerations in a TEMS environment. Rapid decontamination must be taught and practiced by tactical teams because adequate decontamination is usually not available in the inner perimeter.6,3,6

Forensic Science
Basic knowledge of forensic science is important in order to recognize and preserve evidentiary items. Documentation of wound and blood patterns should be done. All evidence should be collected appropriately and the chain of custody honored.6

Medical Threat Assessment
Medical threat assessment (MTA) is the accounting for all variables that may affect the health and welfare of the tactical team, the perpetrators, nearby civilians, and possible hostages. The MTA is an essential component of the preplanning phase and should be integrated into the tactical operation.5,5,6,6 Once the MTA is complete, a plan is then developed based on the medical intelligence addressing each possible situation, with the realization that the plan may change as the mission evolves.

Preventative Medicine
The maintenance of the tactical team’s health is an important aspect of a TEMS program. Poor health has been shown to directly correlate with poor job performance and mission failure.6,5,6

Liability
Because special operations lend themselves to high litigation and possible disability, TEMS providers need to ensure they have proper malpractice and disability coverage.5,7

Urban Search and Rescue
It was hard to breathe. The air was thick and choking. It looked as though black snow had fallen, covering everything.

Remote perspective
It was as dark as a tunnel and the air was as thick as soup. Despite repeatedly scooping chunks of dust and debris from my mouth and nostrils, I inhaled and swallowed large quantities.

Remote perspective
It took an hour to wash off the layers of dust, which by now had become like a layer of concrete.

Remote perspective
Drs. Kelly and Prezant, New York City Fire Department, during the September 11, 2001, terrorist attacks.

Components and Structure of a US&R Team
The responding team must mobilize quickly to accomplish its objectives and must not place additional demands on the already stressed infrastructure. Figure 192-3 shows the organizational structure of a Federal Emergency Management Agency (FEMA) US&R team.2,7 There are 28 FEMA US&R task forces throughout the continental United States that are trained and equipped to handle structural collapse.

An effective US&R team needs both properly trained personnel and appropriate equipment. The equipment cache should allow the task force to be totally self-sufficient for the first 72 hours and to be capable of 24-hour operation for 10 days.7,7 The FEMA equipment cache is divided into five groups—rescue equipment, medical equipment, technical equipment, communications equipment, and logistics equipment. The medical equipment cache was designed to treat the unique medical needs of trapped victims as well as the medical needs of the team. The medical cache contains enough supplies to handle 10 critical cases, 15 moderate cases, and 25 minor cases. The cost of the entire cache is approximately $2 million.7,7

Coordination and cooperation with local resources and other teams is critical.7,7 The US&R team is integrated into the Incident Command System (ICS) at the disaster.

The search team is responsible for developing and implementing a plan to search the area for victims. The search team can be subdivided into two teams—a canine search team and a technical search team. The canine team uses specially trained
dogs to locate trapped victims. The technical team uses specialized microphones, listening devices, cameras, and fiberoptic devices to locate victims in confined spaces. The search team is responsible for locating victims and identifying probable areas where victims may be found.

The rescue team is composed of rescue specialists. Once a victim or potential victim is located, the rescue team is responsible for breaching the area and creating a safe entrance to, and exit from, the victim’s position.

The technical team is composed of various specialists, including structural specialists, hazardous materials specialists, heavy rigging and equipment specialists, technical information specialists, and communications specialists. These specialists work collaboratively to ensure a safe and efficient operation.

The logistics team is responsible for all the equipment needs, including inventory, issuing, and record keeping.

Finally, the medical component is composed of medical personnel who are responsible for the medical needs of both the task force personnel and the victims. Typically, the medical personnel are emergency physicians and paramedics.

Medical Team Operations in Urban Search and Rescue

A number of unique considerations must be addressed for US&R. As with TEMS, team physicians must realize that they will be operating outside of their usual environment and that they are not in charge overall. Typically, the physician on the team works with the team leader and the managers of the other components. To do this efficiently, the physician should be familiar with the capabilities and training of all the members on the team and the ICS. Cross-training of team members is ideal.

Medical Team Tasks

Predeployment. The job of the medical team in the predeployment phase is to ensure that the entire team is fit and functional for deployment and that the medical equipment cache is organized and up-to-date. The perceived medical threats in the deployed area must also be addressed (e.g., endemic disease, water contamination, insect threats, existing medical support, etc.). A family and communication support system should also be set up before the deployment.

Deployment. The medical team is responsible for much more than just treating the victims. Medical intelligence information needs to be collected and addressed (Box 192-1). A plan is required for transfer and transport of victims and for fatality management.

The medical action plan is critical for ensuring smooth operations and must be updated as conditions or knowledge changes. The medical component of a US&R team needs to be able to provide care for its own team members, whose needs may exceed those of the victims. The medical team also needs to assess the adequacy of team members’ rest and sleep and the psychological effects of the situation. In addition, the US&R medical assets must be integrated with the overall medical response that is guided under Emergency Support Function Number 8, “Public Health and Medical.” This includes integration with existing medical resources, disaster medical assistance teams, TEMS resources, military resources, and public health. If there is a canine search component, the medical team should receive some sort of basic veterinary training before deployment.

Confined Space Issues

A confined space is defined as any space with limited access and ventilation. The physician and medical team must be prepared to work in this setting during a deployment and must be aware of issues related to team and victim safety, air purification, and structural dynamics related to collapse or impending collapse.
Specific Disorders in Urban Search and Rescue

US&R teams will typically be responding to the aftermath of earthquakes, collapsed structures, terrorist bombings, hurricanes, and other natural and man-made disasters. Reviews of the literature have identified the types of medical problems and conditions that might be encountered. Most of the medical conditions are those encountered in the emergency department and are handled similarly. The following clinical problems occur with much greater frequency in the US&R environment: crush syndrome, compartment syndrome, particulate inhalation, hazardous materials exposures, and blast injuries. Since the terrorist attacks of September 11, 2001, there has also been an emphasis on preparing the US&R teams for the medical response to weapons of mass destruction.

Crush Injury and Crush Syndrome

Compartment syndrome is defined as crush injury caused by swelling of tissue inside the confining fibrous sheath of a muscle compartment, which can cause further destruction of the intracompartment muscle and nerves. Compartment syndrome is discussed in Chapter 46.

Crush syndrome is defined as the systemic manifestations caused by crushed muscle tissue. This typically occurs when blood flow is restored to the crushed tissue and the toxins are released systemically. It is estimated that 3 to 20% of earthquake victims, and up to 40% of survivors of multistory building collapses, will develop crush syndrome. Early hydration of the victim in the rubble before, during, and after extrication can lessen the renal effects of crush syndrome.

Crush injury and crush syndrome can result from objects that have fallen on the patient or from the patient’s own body weight. The amount of time required for crush syndrome to develop depends on both the amount of pressure and patient factors. It can occur within 1 hour if the pressure is severe, but it usually takes 4 to 6 hours to develop.

Pathophysiology of Crush Syndrome. The cause of muscular injury in crush injury is not fully understood and controversial. The intracellular contents of the cell include lactic acid, potassium, myoglobin, uric acid, enzymes, leukotrienes, thromboxane, phosphate, and others. There is also increased capillary permeability. This can lead to edema and third spacing of fluid. These effects occur locally until the tissue is released and reperfused. This is why victims can be trapped for days with severe crush injury and appear stable when reached by rescuers only to deteriorate soon after being rescued. There are reports of patients going into cardiac arrest soon after rescue. When the crushed area is released, there is a release of all the intracellular contents that have been building up locally into the systemic circulation, causing systemic symptoms. The major causes of early death due to crush syndrome are hypovolemia due to third spacing of fluid and dysrhythmias due to severe metabolic acidosis and hyperkalemia. Delayed causes of death include renal failure, acute respiratory distress syndrome, sepsis, ischemic organ injury, disseminated intravascular coagulopathy, and electrolyte disturbances.

Management of Crush Syndrome. Early aggressive therapy is essential for prevention of crush syndrome, and it should begin before extrication. All victims who have an obvious crush injury or are immobilized for 4 hours or more should be considered to have crush injury. The severity of the crush syndrome may be related to the number of extremities with crush injury. In a Japanese study of earthquake victims, the incidence of acute renal failure due to crush syndrome was 50% for one involved extremity, 75% for two involved extremities, and 100% for three or more involved extremities. Once a victim is located, the medical component needs to be actively involved with the rescue process and begin treatment before extrication. Cardiovascular instability is commonly seen in crush syndrome. As extrication is being done, continuous cardiac monitoring is recommended. Adequate hydration is recommended along with the usual management of hyperkalemia (e.g., insulin/glucose, ion exchange resins, beta-agonists, and dialysis). The current guidelines taught in the FEMA medical specialists course recommend IV calcium only for arrhythmias that do not respond to other measures or when there is a documented severe hypocalcemia. It has been suggested that an average-sized adult may require up to 12 L/day of fluids to sustain a forced diuresis of 8 L/day to prevent renal complications. Continued monitoring of the patient’s vital signs, hydration status, and urine output should be done to guide fluid administration until more invasive monitoring is available. Alkalinization of the urine to prevent renal failure has been recommended in crush syndrome but has not been subjected to proper study, and the effects of the alkalinization, if any, are impossible to separate from those of the volume fluid used. Rhabdomyolysis and its relationship to renal failure are discussed in Chapter 125.

Other Medical Problems in US&R

Another unique medical problem in US&R is dust and airway contamination. During earthquakes and building collapses, a tremendous amount of dust is released into the air. During the first 48 hours of rescue efforts at the World Trade Center (WTC), 90% of the 10,116 New York City Fire Department rescue workers evaluated at the WTC site reported an acute cough often accompanied by nasal congestion, chest tightness, or chest burning, but only 3 required hospitalization for respiratory symptoms (Fig. 192–4). During the 6 months after the attacks, 322 firefighters and one EMS worker had WTC-related cough severe enough to require more than 4 weeks of sick leave. The victim of a collapsed structure should be assumed to have some sort of dust contamination. Evaluate the airway for any evidence of burns or hazardous materials exposure. During the extrication process, monitor the patient’s airway and be prepared for deterioration. If considering intubation, it is better to do it early before edema obstructs the
airway, making the procedure more difficult. Medical manage-
ment of the victim reached after prolonged entrapment is very
different from the typical trauma setting. The “scoop and run”
approach of the trauma patient is not always appropriate or
possible.

Hypothermia may also be an issue for patients subjected
to environmental conditions. Stabilization, extrication, and
ongoing treatment should also be directed at the prevention
or reversal of hypothermia, as discussed previously.

The references for this chapter can be found online by accessing the
accompanying Expert Consult website.
Disasters occur in all areas of the world and cause harm to people, property, infrastructures, economies, and the environment. Harm to people includes death, injury, disease, malnutrition, and psychological stress. Recent catastrophes include earthquakes in Iran (2003) and Pakistan (2005) (Fig. 193-1); devastating tsunamis in the Indian Ocean involving multiple countries, including Sri Lanka, Indonesia, and India (2004); massive hurricanes in the southern United States (2005); severe flooding in Mozambique (2000) and France (2003); tornadoes in Arkansas, Tennessee, and Kentucky (2008); and global adverse weather conditions related to the El Niño phenomenon (2003 and 2004). These types of events are likely to become more common in the future. Increasing population density in floodplains and in earthquake- and hurricane-prone areas and the effects of global warming point to the probability of future catastrophic disasters with millions of casualties.

Factors that indicate an increasing probability of mass casualty incidents include (1) terrorist activity; (2) increasing population density in floodplains, seismic zones, and areas susceptible to hurricanes; (3) production and transportation of thousands of toxic and hazardous materials; (4) risks associated with fixed-site nuclear and chemical facilities; (5) the possibility of catastrophic fires and explosions; and (6) global warming. For example, the U.S. Geological Survey has identified approximately 35 volcanoes in the western United States and Alaska that are likely to erupt in the future. Mt. Hood, Mt. Shasta, and the volcano underlying Mammoth Lakes in California are near population centers. Because of the rising population density in these areas, hazards from volcanic activity are increasing.

A committed emergency department alone is insufficient to provide hospitals with a successful disaster preparedness program. Institutional commitment by every hospital department and the administration is necessary to coordinate effectively with systemwide resources for disaster management. This is especially critical for creation of hospital surge capacity.2,4

### Surge Capacity

The concept of surge capacity has emerged as a way to manage an event that produces a sudden influx of casualties with medical and health needs that exceed current hospital resources.5 This can occur due to either the volume or types of victims. The three basic components of the surge capacity system are commonly referred to as the three S’s of staff (hospital personnel), stuff (supplies and pharmaceuticals), and structure (physical location and management infrastructure). A complete discussion of surge capacity is beyond the scope of this chapter but has been published elsewhere.3,4

### Nature of Disasters

#### Definitions

One of the challenges facing those responsible for disaster preparation is that no standard definition of disaster exists. Some events that have been routinely classified as disasters clearly are not. For example, many would consider a plane crash a disaster, yet it may not even approach overwhelming the resources of the local responders. Because disaster medicine is multidisciplinary and depends on the integration of multiple levels of responders, the use of a common, precise terminology is essential.

In general terms, an event can be considered a disaster when it overwhelms response capabilities. These response capabilities can change in diverse environments or even in the same location at different times of the day or days of the week. For example, a multiple-vehicle collision with 6 critically injured patients and 12 patients with minor injuries could overwhelm both the emergency medical services system and the hospital in a small rural community. In an urban area with multiple hospitals that participate in a trauma system, however, this same event could be handled with routine resources. Thus, it is the functional impact on the specific area that is the key concept in determining whether a disaster exists.
Chapter 193 / Disaster Preparedness

2485

Figure 193-1. Large-scale catastrophes, such as this earthquake in Pakistan (2005), have the potential to cause much injury and psychological stress.

Classic Terminology

Many terms have been used in an attempt to describe disasters. The words *internal* and *external* refer to a hospital setting to help distinguish whether an event has occurred within the hospital grounds (internal) or in the community (external). This concept distinguishes between preparing for casualties to arrive at the hospital and dealing with casualties or resource problems within the hospital. This geographic distinction between internal and external may be useful, but it has severe limitations. Many events can be both internal and external to the facility at the same time (e.g., major earthquake or hurricane). Furthermore, simply identifying the location of the event does not answer the critical question: How are response capabilities affected?

An etiologic descriptor for an event is another customary classification. It does not matter whether a disruption in the ability of the hospital to respond is caused by nature or by humankind. The key consideration is what needs to be done to mitigate and then to rectify the situation. Thus, although the terms *natural* and *man-made* are prevalent disaster descriptors, they generally do not add anything of value and therefore some experts have advocated to remove them from the disaster lexicon, particularly because the cause of the event may be unclear in its initial aftermath.

Some definitions have been based on the number of casualties. As previously described, the absolute number of patients is much less important than whether their medical and health needs exceed the resources to care for them. Another scheme divides disasters into three levels. Level I denotes a situation in which local resources are adequate to care for casualties. For example, the 2002 collision between a freight train and commuter train in Orange County, California, was managed effectively by local responders. Level II means that regional mutual aid is required to respond to the event. This was the case at the Hyatt Regency Hotel in Kansas City in 1981 when two skywalks collapsed, killing 114 people and injuring hundreds. Level III incidents require state and federal aid. The attack on the World Trade Center in 2001 (Fig. 193-2) and Hurricane Katrina in 2005 were such events, causing such massive destruction that federal disaster medical assistance teams were deployed to New York and Louisiana, respectively, to provide medical personnel and supplies.

One model eliminates the word *disaster* and replaces it with the acronym for potential injury-creating event, *PICE.* The PICE nomenclature is an attempt to resolve the issue regarding diverse meanings for *disaster.* This model is referenced in the Joint Commission standards and in publications from several countries. The PICE system is discussed here to help clarify important concepts in describing an event.

Potential Injury-Creating Event Nomenclature

The acronym PICE and its modifiers concisely describe the critical features of most types or degrees of disaster. The same occurrence can have different effects at different points in time; thus, as an event evolves over time, its description may change.

Modifiers are chosen from a standardized group of prefixes along with a stage to indicate the need for outside medical assistance (Table 193-1). The first prefix (column A) describes the potential for additional casualties. The second prefix (column B) describes whether local resources are overwhelmed and, if so, whether they must simply be augmented (disruptive) or whether they must first be totally reconstituted (paralytic). The third prefix (column C) shows the extent of geographic involvement.

The stage rating scale defines the likelihood that outside medical assistance will be needed either to augment or to completely reconstitute resources. Stage 0 means that there is little or no chance. Stage I means that there is a small chance and requires placing outside medical help on alert. Stage II means that there is a moderate chance and outside help should be placed on standby. Stage III means local resources are clearly overwhelmed and requires the dispatch of outside resources and commitment of personnel. For example, a multi-vehicle collision with a dozen injuries and several deaths in a large city would be a stage 0, whereas in a small rural town it might be a stage III (Table 193-2).

A PICE can be either static or dynamic. *Dynamic* implies an evolving situation in which it is too soon after the incident to determine the numbers and types of casualties and the impact on the hospital. Alternatively, a *static* situation results if 10

Figure 193-2. The World Trade Center attack of 2001 overwhelmed local resources and necessitated state and federal help.
people are injured in an incident and little potential for further harm exists.6-8 In some situations, enhancing routine operations is not sufficient or possible. A PICE can completely overwhelm the capability to mount a normal response so that a substitute plan for recovery must be used. Situations that require significant reconstitution of critical resources are termed paralytic.6-8 Within the hospital, there are six critical elements necessary to provide a response (Box 193-1).9 If one or more of these resources are compromised, they must be reconstituted or a substitute must be implemented. Such paralytic events can be either destructive or nondestructive (Box 193-2).6

### Hazard Vulnerability Analysis

An important consideration in disaster planning is an awareness of the types of events for which the hospital or community is vulnerable. The classic example is the monumental risk from earthquakes in the central United States resulting from the combination of the New Madrid fault and the limited seismic safety requirements for buildings in that area. The planner must learn what types of support are available from outside agencies (e.g., hazardous materials decontamination from fire departments and information from poison control centers). Although awareness of such resources is critical, contingency plans must be available when such assistance is not accessible.

After performing a hazard vulnerability analysis, emergency planners should consider the most probable events and prepare for them. There must also be planning for events that are rare but catastrophic.10 The major peacetime threat to life and limb in the United States is probably a large earthquake in a densely populated area or a terrorist attack. The disaster planner must proactively identify all such hazards and prepare contingency plans for each.

### Triage

The term *triage* derives from the French verb, *trier*, meaning “to sort.” The concept of triage was used as far back as Napoleon’s time to assign priorities to treatment of the injured when resources were limited. Priority is given to the most salvageable patients with the most urgent conditions. The emergency department uses triage in the hospital setting on a daily basis, but the focus of such triage must be changed under disaster conditions.11,12 Standard emergency department triage is intended to identify the most seriously ill patients first and ensure that they receive rapid care. The goal of disaster triage is slightly different—that is, “to do the most good for the most people.” In other words, there is a shift from focus on individual patients to focus on the entire affected population. It can be very difficult for physicians to realize that to achieve the goal of maximizing benefit to an entire population of patients, they may need to let some patients die with only comfort care. Under true disaster conditions, cardiopulmonary resuscitation should not be performed.13

### Routine Multiple-Casualty Triage

To assist in understanding triage techniques, it is useful to consider a routine out-of-hospital event with multiple casualties (e.g., a multivehicle collision). In such situations, rescue personnel often use a Simple Triage and Rapid Treatment (START) technique that depends on a quick assessment of respiration, perfusion, and mental status.14 Initially, all victims who are able to walk are asked to move away from the immediate incident area. These patients are classified as green, or “walking wounded,” and are reassessed after the more immediately critical patients are triaged.
Catastrophic Casualty Management

Triage during a widespread, catastrophic disaster differs from triage performed in routine out-of-hospital and hospital settings. The number of victims is vastly increased, and medical resources are severely limited or even initially absent. Patients may remain on scene for an extended period and must be frequently reassessed. In addition, the triage process is decentralized, occurring at multiple sites, or compartments, simultaneously throughout the disaster zone. Rather than a single scene or localized disaster, this can be thought of as a compartmentalized disaster. Lastly, patients tend to seek care at the closest hospital, a phenomenon known as convergence. Hospitals close to the disaster scene are overwhelmed, whereas hospitals located only a few miles away may receive few, if any, patients.

To address these considerations, the secondary assessment of victim endpoint (SAVE) system of triage was developed. The SAVE triage system is designed to identify patients who are most likely to benefit from care available under austere field conditions in a resource-poor environment. When combined with the START protocol, SAVE triage is useful for any scenario in which multiple patients experience a prolonged delay in accessing definitive care.

The SAVE methodology is designed for use by health care providers under two conditions: (1) for those working within the disaster zone who begin caring for patients immediately but may not be able to transport patients to a definitive care facility for days, and (2) for those caring for patients within hospitals where demand for resources exceeds supply. This second situation can occur as hospitals attempt to increase surge capacity. It is immediate and dynamic rather than delayed and static. Although there are many elements in common with other triage systems, rapid transport to a functional medical center within the ideal “golden hour” may not be possible.

The SAVE triage methodology divides patients into three categories: (1) those who will die regardless of how much care they receive, (2) those who will survive whether or not they receive care, and (3) those who will benefit significantly from austere field interventions. Only those patients expected to improve receive more than basic care and comfort measures. Using SAVE, patients are separated into these three categories so resources can be focused appropriately. The decision to place patients in a particular group is based on field outcome expectations derived from existing survival and morbidity statistics. An example is a situation in which multiple patients experience a prolonged delay in accessing definitive care.

During the triage process, individuals who would most benefit from early transport should be marked as “first out,” in case an evacuation opportunity occurs. These would be victims with medical problems readily treatable at a hospital but untreatable and fatal in the field. A patient requiring surgery for intra-abdominal hemorrhage is a common example.

Since nuclear, biologic, and chemical terrorism has become a threat, new triage systems are under development. These systems attempt to incorporate the added threats from exposure and contamination into the triage process. One such method for biological casualties triages many individuals to home observation rather than hospitalization to optimize resource utilization and minimize the spread of the infectious agent. In addition, responders must be protected from secondary contamination or exposure; therefore, part of the triage algorithm must include a risk assessment and determination of whether, and what type of, personal protective equipment...
must be donned prior to assessing patients. A quick determination is critical to prevent patient deaths from traumatic injuries while awaiting medical care from responders concerned about their own health and safety. This is particularly true in a “combined event” scenario such as an event involving a radiologic dispersion device. Also associated with terrorism incidents are large numbers of psychogenic casualties—those who believe they were exposed but actually were not and those at risk for post-traumatic stress disorder. The emergency plan must include a mechanism to assess and sort these individuals so as not to overwhelm the emergency department and also provide mental health care. While performing triage, the emergency physician must also consider the effects of extremes of age, underlying disease, and multiple injuries when assessing the potential prognosis for a given patient. Fortunately, the treatment of many nontraumatic emergencies can be accomplished with field interventions that do not consume extensive resources. Therefore, patients with such illnesses should usually be triaged to the treatment area.

Special Triage Categories

To maximize personnel resources, disaster victims who would normally be triaged to the observation area can be triaged to the treatment area if they possess special skills valuable to the medical team (e.g., medical expertise and translation skills). By increasing the number of functional team members, the effectiveness of the overall response will improve. The guiding principle supports the disaster triage goal of maximizing benefit to the most people.

OUT-OF-HOSPITAL RESPONSE

Emergency Medical Services System Protocols

To prepare adequately, hospitals must be familiar with and involved in the development of county or regional plans. For example, some emergency medical services systems use automatic systems such that each hospital may be expected to accept a predetermined number of critically ill or injured and minor patients without previous notification.

Physicians working at hospitals should be familiar with community disaster management operations, including the function of the emergency operations center.9 Mutual aid agreements with other hospitals or regions should be considered for situations in which the hospitals become overwhelmed or require evacuation.

Incident Command System

Some form of an incident management system is now a standard component of emergency command and control throughout the United States. It provides a flexible management structure on which to organize a response.20 The federal version, known as the National Incident Management System (NIMS), is incorporated into the National Response Framework and provides strategic guidance on the U.S. government’s involvement in disaster response. All states must utilize an incident management system, and it must be compliant with NIMS.21 By standardizing an organizational structure and using common terminology, an incident command system provides a management configuration that is adaptable to events involving a multiagency or multijurisdictional response. At the most basic level, there are five functional elements in the organizational structure: (1) incident command, (2) operations, (3) planning, (4) logistics, and (5) finance. The principles of an incident command system can also be applied to the hospital setting through implementation of a Hospital Incident Command System. With this type of organizational infrastructure and the flexibility to expand and collapse as needed, an orderly and efficient response to any incident can be accomplished. Because hospitals cannot anticipate every contingency, a system such as the Hospital Incident Command System assists with planned improvisation. The Joint Commission (formerly known as JCAHO) standards require use of an incident management system in health care facilities.
Chapter 193 / Disaster Preparedness

Operations Section

The operations section has a chief who is responsible for the management of all incident tactical activities. This section can be expanded and subdivided into branches (e.g., law, fire, and medical) and divisions. Operations also manages the resources assigned to staging areas. Ambulances, personnel, and supplies must be staged outside the perimeter of the scene and directed in as needed rather than converging on the disaster site, potentially disrupting activities and blocking the exodus of patients. It is under the operations section that all medical triage and care is provided.

Planning Section

The planning section collects, evaluates, and disseminates information regarding incident operations and the status of resources. This section also develops incident action plans and conducts planning meetings.

Logistics Section

The logistics section’s chief is responsible for providing facilities, services, and material in support of the incident. This includes procuring equipment and supplies, providing food and medical support, and meeting transportation needs.

Finance Section

The finance section is responsible for maintaining records on personnel and equipment, providing payments to vendors for supplies and use of equipment, and determining the cost of various alternatives for strategic planning.

Organization of the Out-of-Hospital Disaster Scene

The disaster site is organized into several distinct areas. The command post is the nerve center of the operation and contains the incident commander and section chiefs. A staging area for incoming personnel and equipment should be established on the outer perimeter. If air evacuation is needed, a safe landing zone must be identified. A casualty collection point and morgue should be designated. In conjunction with an incident command system, this structure brings order to the response.

PLANNING AND HOSPITAL RESPONSE

Comprehensive Emergency Management

The comprehensive emergency management all-hazard approach to disaster preparedness is now required by the Joint Commission. Comprehensive emergency management consists of four phases: (1) mitigation, (2) preparedness, (3) response, and (4) recovery. Mitigation involves taking actions to reduce the impact of identified hazards. Response includes assessment of the situation and coordinating resources. Finally, recovery consists of a return to normal operations and debriefing to critique the response and provide psychological support to the rescuers.

As required by the Joint Commission, a hospital’s disaster or “emergency management” plan must address events that occur both inside (internal) and outside (external) the institution. Because some incidents affect both internal and exter-
Hospital Disaster Response Plan

A disaster event can disrupt daily, routine hospital functions. This can represent an infrastructure failure (e.g., loss of electric power and water) or a threat to the safety of patients and hospital personnel (e.g., labor dispute). Because the response varies from postponing elective surgery to facility evacuation, every hospital department must participate in the planning process. At a minimum, the disaster plan should (1) clearly delineate the circumstances in which the plan is activated; (2) identify the command structure with defined lines of authority and responsibility; (3) describe a response strategy for each anticipated incident; (4) estimate an incident’s impact on safety and hospital function, providing for evacuation if necessary; and (5) list essential information, such as critical telephone numbers (e.g., elevators, key personnel, and pay telephones), community agencies (emergency medical services, police, and public health), and sources of vital supplies (water, oxygen, and drugs).22

After plan activation, the primary role of the emergency department is to assess and treat individuals with illness or injury. In the absence of casualties, other hospital departments primarily manage disasters that disrupt hospital operations. Nevertheless, the medical director of the emergency department should continuously monitor the response process.

In the unlikely event that evacuation of the emergency department is necessary, evacuation routes and relocation destinations that have been planned in advance maximize safety and efficiency. When resources are plentiful, emergency department patients in critical condition are assigned the highest priority for evacuation and transport. Less ill patients receive a lower priority.24 When resources are limited (e.g., in the event of a large-magnitude earthquake), the reverse strategy applies. The least critically ill patients receive the highest priority for evacuation.

Another scenario would be an event occurring in the community that results in a sudden influx of patients requiring emergency care at hospitals. This type of incident has no direct impact on hospital capacity or function. Participation in the planning and execution of the hospital disaster response is an important administrative responsibility.13 Available data guiding development of disaster strategies are incomplete, but an effective disaster response can be created by reviewing the essential components of disaster plans and the previous experience of hospitals.13,22,24 A member of the emergency department must have a leadership role in the planning and implementation of the disaster plans.

Basic Components of a Hospital Comprehensive Disaster Response Planning Process

Interdepartmental Planning Group

The interdepartmental planning group has the responsibility for hazard identification and disaster preparedness activities. Frequently referred to as the disaster or emergency preparedness committee, it is composed of representatives from all departments vital to the hospital’s response, including administration, medical staff, nursing, safety, security, the emergency department, and engineering. Additional input may occasionally be necessary from outside agencies (e.g., fire department, hospital suppliers of goods and services, and emergency medical services agency).

The committee must be structured to ensure that the plan is properly constructed, tested, and executed. Hospital resources must be provided to support the planning process and testing of the plan, and there must be a detailed educational program for all affected hospital staff.23,25

Resource Management

A full inventory of the hospital’s resources must be available. In addition to equipment, space, and personnel within the institution, potential support from outside the hospital must be sought. It is also necessary to develop contingency plans to compensate for lost resources (e.g., failure of hospital computers during a power outage). Augmentation of such resources is critical to successfully increase the hospital’s surge capacity.3,4,26

Strong relationships with community agencies (e.g., fire department and regional emergency medical services system) are important to ensure a coordinated disaster response. Hospitals located near companies using large amounts of hazardous materials are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning committees.27

Command Structure

An organized system establishing lines of authority and decision responsibility must be in place. This system should designate a command center where the disaster response can be coordinated and create a clear chain of command. This prevents confusion if certain individuals are missing, a common situation on nights and weekends. The command center should contain sufficient equipment to support command and control functions, even if the center must be moved as a result of hospital damage.

Media

The media can be an important source of information but can also significantly disrupt the hospital’s disaster response. Therefore, arrangements should be made in advance for a designated individual to coordinate all media interactions and for these briefings to occur in a designated location. Media coordinators should inform reporters of the time they will receive their next update so they do not intrude on response operations while trying to obtain information. A strong media liaison can facilitate dissemination of important information to the public, such as that no blood shortage exists so that individuals refrain from coming to the hospital to donate blood. In fact, crisis and emergency health risk communication is now an important part of managing the disaster response and can significantly impact the public’s perception of events.28 Security should be involved in managing the media response to the hospital and in preventing media from interfering with triage and treatment of patients.

Communication

Communication systems are probably the most important, but also most vulnerable, component of a disaster plan.13,25 Redundant systems are essential. Those responsible for mobilizing the emergency response require access to at least one other communication system besides the telephone (which is frequently one of the first systems compromised during a disaster). Two-way radios are often used, as are pay telephones, independent fax lines, and cellular phones. Another option is the use of satellite phones and wireless hand-held devices to
Personnel

The disaster plan must include a roster of all critical positions and personnel and establish a reliable method for their mobilization. Several individuals should be assigned to each position in case some personnel cannot be reached. A protocol for managing volunteers is also crucial. A large group of uncontrolled volunteers descending on a hospital can be as disruptive as the disaster.

Credentialing volunteer health professionals in a timely manner so hospitals can utilize their services during a disaster remains a challenge. A federally supported program known as the Emergency System for Advance Registration of Volunteer Health Professionals (ESAR-VHP) is attempting to address this problem. When completed, it will provide a system for credentialing volunteer health care providers in advance of a disaster so they will have emergency privileges should the need for their services arise. There remain significant challenges with such a system, including whether sufficient numbers of providers will participate, how well qualified they will be, and whether they will have competing obligations during a disaster. An alternative system that permits hospitals to recognize each other’s credentialing process through a shared database shows promise. Not only will this alternative system facilitate participation by most health care providers but also it permits hospitals to grant emergency privileges within minutes after a disaster.

Patient Management

A systematic approach to patient management is necessary to maximize resources. This includes protocols for decontamination, triage, patient prioritization, evacuation, and control of patients’ families. Alternative use of hospital facilities must be anticipated, such as the conversion of a parking lot into a clinic area for suturing lacerations or a decontamination zone. Provisions for patient identification and treatment documentation are also important to facilitate federal and third-party reimbursement at the conclusion of the disaster.

Training Exercises

Disaster exercises are one of the more effective ways of familiarizing hospital staff with their responsibilities. All hospital departments should participate, and community agencies should be involved. The Joint Commission requires two drills a year; these should mimic incidents that are likely to occur.

REVIEW OF HOSPITAL AND COMMUNITY DISASTER RESPONSE EXPERIENCE

Disaster plan implementation is complex and difficult. Much can be learned from reviewing previous disaster response experiences, resulting in improved implementation strategies. The following discussion highlights potential problem areas.

Focal Disasters

Most disasters experienced by hospitals are focal in nature. Hospital function is typically unimpaired. The majority of problems encountered are related to a sudden increase in patient volume and acuity or arrival of patients with illnesses not usually treated at that facility (e.g., burns, radiation exposure, and severe acute respiratory syndrome).

Hospitals frequently experience difficulty in effectively using and interfacing with community resources. Field triage must allocate patientsrationally, and transfer agreements must be in place to facilitate interhospital movement of patients and evacuation of patients to alternate care sites.

Media access must be controlled. During the Loma Prieta earthquake in 1989, a news helicopter occupied a nearby community hospital’s only landing zone, preventing the possibility of landing a medical helicopter.

Redundant communication systems must be in place. Typical backup systems to the telephone are radios and cellular phones, but the frequencies can be overloaded in both systems. Two-way radios are reliable and should be part of the communications network. Satellite phones are also an option.

Catastrophic Disasters

In a large-scale disaster, paramedics may be unavailable to assist in patient transfers or hospital evacuations. Disaster medical assistance teams and urban search and rescue teams will deploy, but their time to arrival on scene may be variable. Each individual hospital may have to remain self-sufficient for 48 to 72 hours or longer. Generator problems are frequent; they either fail altogether (as they did during the Loma Prieta earthquake) or supply insufficient power to meet emergency needs (as during the Northridge earthquake). Evacuation plans must not require elevators for this reason. Telephone service will cease as lines are disrupted or deliberately restricted by the phone company. Cellular phones may function within a local area, but failure is likely if more distant sites within the city are dialed. Hospital radios designated for disaster use must have the hardware secured to prevent earthquake damage.

Under catastrophic conditions, mobilizing personnel is more difficult. Because telephone communication is unreliable, at least one additional system for contacting personnel at home must be in place. An alternative is to institute an automatic response system.

After earthquakes or explosions, immediate access to structural engineers is important. In the Northridge earthquake, eight hospitals in the Los Angeles area sustained enough damage to force evacuation of at least one patient. Four institutions completely evacuated their facilities in the first 24 hours, including two hospitals that met the most current structural earthquake standards. Further structural damage was subsequently identified, and two additional hospitals were forced to evacuate completely in the next 2 weeks. Ultimately, four of these hospitals were permanently closed and demolished.

Catastrophic earthquakes can cause extensive casualties, including large numbers of patients with crush syndrome and lacerations. Up to 90% of victims with serious but survivable injuries are rescued by local responders and volunteer citizens in the first 24 to 48 hours. Therefore, special medical teams such as disaster medical assistance teams and urban search and rescue teams may not significantly affect survival if they arrive after more than 48 to 72 hours. If hospitals are not functional and no backup plan exists, immediate advanced medical care will not be available, and many people will die. Therefore, planners must include a backup system to provide medical care at nonhospital alternate care sites.

Need for Local Response

Currently, it is not possible for outside assistance to arrive in force during the crucial first 48 hours. Therefore, an alternative source of immediate, sophisticated medical care is necessary.
It appears this is best provided by local responders who can begin caring for patients soon after the event. The Medical Disaster Response Project is the most advanced model of a local medical response to such a disaster. Developed by emergency physicians in Southern California, the Medical Disaster Response Project has two components: (1) training of health care providers in the management of disaster victims under austere conditions and (2) placement of sophisticated medical supplies at designated sites within the community. Under this plan, victims could receive rapid, advanced medical care from surviving volunteer health care providers even if hospitals were destroyed.

## Toxic Disasters (Hazardous Material)

Hospitals in the vicinity of major chemical industries, transportation corridors, or probable terrorist targets (e.g., major theme parks or nationally symbolic buildings) should be aware of potential hazards from incidents involving chemical and radioactive substances and be prepared to decontaminate large numbers of individuals exposed to these hazardous substances. Effective decontamination of victims and the need for safety measures on the part of rescue personnel to prevent secondary contamination are critical. Decontamination equipment must be stored near the emergency department, and the staff must be trained in its use. This location must be known to personnel. When such an emergency occurs, there is little time to search the hospital for the necessary supplies.

Ideally, patients contaminated with hazardous chemicals should first be brought to a designated decontamination area containing a warm water shower with a container to hold drainaget water. Victims should remove all clothing. Clothing and valuables are bagged, tagged, and stored. Contaminated patients must never be brought into regular patient care areas because of the danger of contaminating other patients, hospital staff, and equipment. In 1994, paramedics unsuspectingly transported a patient contaminated with a degradation product of dimethyl sulfoxide to an emergency department in Riverside, California. Before detecting the presence of the hazardous material, six health care workers were exposed, including an emergency physician. The emergency physician experienced a near-fatal exposure and required intubation and an extensive stay in the hospital’s intensive care unit. Uncontrolled spread of the toxin resulted in evacuation and temporary closure of the emergency department.

The emergency department must close off the air intake vents in rooms containing contaminated patients so toxic products do not enter the ventilation system and circulate to other areas of the hospital. Rescue personnel and hospital staff should be protected by gowns, gloves, and masks and, if necessary, supplied air respirators. The goals are to reduce the initial level of external contamination, contain the contamination that remains, and prevent further spread of these potentially dangerous substances to other patients and staff members.

### Chemical, Biologic, Radiologic, Nuclear, and Explosive Terrorism

In addition to the familiar threat from hazardous materials, there is a new challenge: a potential attack by terrorists using biologic, radiologic, or chemical weapons (see Chapter 194). Although somewhat similar to hazardous materials situations, management of patients exposed to weapons of mass destruction (WMD) requires new knowledge and skills. Expertise in the management of patients attacked with unconventional weapons is important, but emergency physicians should also be familiar with treatment of blast injuries. High explosive events, including suicide bombers, remain the most probable type of terrorism.

The most likely radiation source used by terrorists will probably not come from the detonation of a nuclear weapon. Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are believed to be the source of choice. They do not explode and give no warning of their presence. Terrorists can also dismantle such devices and incorporate the radioactive source into an explosive radiologic dispersion device (“dirty bomb”). Therefore, providers must recognize the presentation of patients suffering from radiation exposure to make the diagnosis. In addition to damage from radiation, these casualties may also suffer blast injuries. Patients who are irradiated but not externally or internally contaminated pose no threat to emergency department personnel.

One of the greatest challenges with respect to WMD is the detection of biologic weapons. Patients exposed to many of the biologic agents initially present with vague symptoms associated with flulike illnesses. Decontamination is not a priority unless the exposure is immediate; standard precautions are generally sufficient.

Unlike radiologic or biologic weapons, chemical agents produce symptoms quickly. The challenge is decontamination and treatment. Approximately 80% of mass casualty decontaminations are performed at hospitals. Therefore, hospitals must be prepared to decontaminate patients outside the emergency department. Personal protective equipment is also an issue for responders because of the risk of exposure during the decontamination process.

### Disaster Stress Management

Emergency health care providers experience high levels of stress responding to the needs of disaster victims. If this excessive stress exceeds the capacity of normal coping mechanisms, it can potentially interfere with job performance and produce disturbing symptoms, including depression, sleep disturbances, increased use of alcohol and drugs, irritability, and anxiety. Post-traumatic stress disorder can result. In an attempt to reduce the psychological impact of these events on medical responders, various therapeutic techniques have been introduced throughout the years and are collectively known as critical incident stress management. This formal process of resolving emotional conflict utilizing mental health professionals is now widely practiced.

In general, the longer the delay between exposure to the critical incident and subsequent psychological intervention, the smaller the chance for a successful outcome. Therefore, the critical incident stress management process is designed for rapid implementation. During the incident, stress management staff or even a colleague can provide on-scene intervention. The goal is to assist the health care worker in regaining emotional control by facilitating communication of feelings and reactions through listening and support.

If a critical incident has profoundly affected participants, and if symptoms are still present many hours later, urgent assistance is provided in the form of defusing. The critical incident defusing process is coordinated by mental health and peer support staff and focuses on information and venting of emotions. This process often takes place away from public view to protect confidentiality. If the psychological stress is severe, the process transitions to formal care provided by psychiatrists or psychologists. Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction.

**Chapter 193 / Disaster Preparedness**

**DISASTER MANAGEMENT AND RESPONSE ORGANIZATIONS WITHIN THE U.S. GOVERNMENT**

**Department of Homeland Security**

The Department of Homeland Security (DHS), a cabinet-level department formed after the terrorist attacks of September 11, 2001, is the federal government’s lead organization for emergency management activities in the United States. The Federal Emergency Management Agency (FEMA) has been incorporated into DHS and retains its name. DHS has a coordinating responsibility for the entire spectrum of disasters irrespective of their size or etiology. DHS assists state and local organizations to mitigate, prepare for, respond to, and recover from emergencies and is a major source of funding for these endeavors. In 2003, the President directed that the DHS develop a National Incident Management System and a National Response Plan. Existing federal plans, including the National Response Plan, were then incorporated into the National Response Framework.

**Urban Search and Rescue**

When a building collapses because of an earthquake, terrorist bombing, structural failure, or other reason, various challenges confront rescue and medical personnel. Some victims require field amputations to facilitate extrication, and use of urban search and rescue teams and effective emergency medical care may improve the outcomes of such lifesaving efforts. This national system of multidisciplinary task forces is designed for rapid deployment to the sites of collapsed structures. The medical team’s responsibilities include caring for task force members, victims recovered by search and rescue activities, and the search team’s dogs. There are now WMD urban search and rescue teams trained by FEMA to respond to nuclear, biologic, and chemical terrorist attacks.

**Department of Health and Human Services**

On December 19, 2006, the President signed the Pandemic and All-Hazards Preparedness Act (S. 3678) into law and created a new position, the Assistant Secretary for Preparedness and Response (ASPR), within the Department of Health and Human Services (DHHS). The office of the ASPR oversees the department’s responsibilities for emergency preparedness and response activities, including the National Disaster Medical System (NDMS) and the Hospital Preparedness Cooperative Agreement Program, the coordination of the Medical Reserve Corps, the ESAR-VHP, the Strategic National Stockpile, and the Cities Readiness Initiative.

**National Disaster Medical System**

The NDMS is a federally coordinated initiative designed to augment the emergency medical response capability of the United States in the event of a catastrophic disaster. This system is a cooperative program of four agencies in the federal government: the Department of Defense, the DHHS, the DHS, and the Department of Veterans Affairs (VA). Although oversight of the NDMS has moved between federal departments, the DHHS currently has the lead for the NDMS. The NDMS provides an interstate medical mutual aid system linking the federal government, state and local agencies, and private sector institutions to address the medical needs of victims of catastrophic disasters. Its medical response element includes dozens of volunteer civilian disaster medical assistance teams that supplement the local medical infrastructure.

In a disaster, the NDMS is activated when state resources are overwhelmed and the governor makes a request for federal assistance. The disaster medical assistance teams must meet specific NDMS standards. Throughout the NDMS, emergency physicians are taking key roles in defining training standards, the deployment of clinical services, and the administration of field operations and in developing the concept of a civilian-federal disaster response capacity during national emergencies.

**Centers for Disease Control and Prevention**

The Centers for Disease Control and Prevention (CDC), based in Atlanta, is a U.S. federal agency under the DHHS. Its major responsibilities include preparing for and responding to public health emergencies (e.g., disasters) and conducting investigations into the health effects and medical consequences of these events. The major aims of CDC researchers are to assess the risks of death and injury and to develop strategies for preventing or mitigating the impact of future disasters. Other responsibilities of CDC staff in the area of emergency preparedness and response include (1) rapid assessment of the health and medical needs of disaster victims in the immediate postdisaster period; (2) development and maintenance of national systems for acute environmental hazard surveillance; and (3) provision of epidemiologic, sanitary, laboratory, and other relevant scientific support services to agencies involved in disaster planning and response.

**Metropolitan Medical Response System**

Metropolitan Medical Strike Teams (MMSTs) are highly trained, readily deployable, and fully equipped groups of medical, fire, and rescue professionals. As a component of the larger Metropolitan Medical Response System (MMRS), they support other local personnel in treating the victims of a chemical, biologic, or nuclear attack. In 2008, the MMRS expanded to include 125 participating jurisdictions. Although composed of local personnel, MMSTs are under the direction of the DHS. Their goal is to enhance local planning and response capability. However, hospital and community planners must still create an independent response because MMSTs require 90 minutes or longer to deploy. MMSTs are equipped with chemical agent monitoring devices, protective equipment, and pharmaceutical supplies.

**Department of Veterans Affairs**

The VA has not traditionally been regarded as a disaster response entity. However, one of the VA’s four mandated missions is emergency management. A unique feature of the VA is that its facilities and personnel are situated nationwide, and these are used to support federal health and medical assistance to state and local governments during disasters. The VA has highly trained specialty personnel who can support disaster medical activities. In addition to the vast pool of human resources, the VA provides large amounts of the pharmaceutical and expendable supplies for on-site disaster support. For example, the VA purchases the contents of the CDC’s Strategic National Stockpile. VA support is coordinated through the DHS and DHHS, as the lead federal agency for health and medical response. In addition to the VA’s role in the federal response to disasters, as the largest integrated health care system in the nation, it has a well-developed hospital emergency management program. The VA Emergency Management Program Guidebook is an open-source reference that provides up-to-date information on emergency management concepts.
and various templates for emergency operations plans and hazard vulnerability assessment tools for hospitals.

The Military

On April 17, 2002, Secretary of Defense Donald Rumsfeld announced the formation of the Northern Command, or NorthCom, to assume responsibility over all military forces that operate within the United States in response to external threats and in support of civil authorities. Furthermore, Secretary Rumsfeld stated that NorthCom will “help the department better deal with natural disasters, attacks on U.S. soil, or other civil difficulties. It will provide for a more coordinated military support to civil authorities such as FBI, FEMA, and state and local governments.”

FUTURE DIRECTIONS

The field of disaster medicine has become a major subspecialty within emergency medicine, and a section for disaster medicine has been organized within the American College of Emergency Physicians and the Society for Academic Emergency Medicine. There are also numerous national and international forums for the presentation of disaster medical research results. Since the American College of Emergency Physicians first defined a disaster medicine curriculum suitable for residencies and fellowships, a number of disaster medicine fellowships have been established in the United States and elsewhere. In the 21st century, disaster medicine will continue to develop as a professional activity and unique academic specialty.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

The practice of emergency medicine now has another challenge: the possibility of an attack by terrorists using nuclear, biologic, chemical, or high-explosive weapons. Although conventional explosives remain the most common weapon used by terrorists, the risk from nuclear, biologic, and chemical agents may increase over time. The nomenclature for these weapons remains controversial. Some authors have proposed the use of weapons of mass effect or weapons of mass disruption. The military uses the acronym CBRNE, pronounced “see-bruh-nee” and referring to chemical, biologic, radiologic, nuclear, and explosive. This chapter uses weapons of mass destruction (WMD) because of its wide acceptance.

The results of an attack with WMD, although admittedly of low probability, are potentially catastrophic. According to a World Health Organization estimate, 50 kg of anthrax spores aerosolized above a city of 5 million people would result in 100,000 deaths, with an additional 150,000 people seriously infected. The cost of managing 100,000 cases of anthrax exposure is estimated at $26 billion by the Centers for Disease Control and Prevention (CDC). Given these considerations, most authorities believe that preparedness for such threats must be improved.

Children are particularly vulnerable to these weapons. They breathe at a faster rate than adults, increasing their relative exposure to aerosolized agents. Some chemicals, such as sarin, are heavier than air, so they tend to accumulate at the level where children are more likely to inhale them. Children have a greater surface area-to-volume ratio and their skin is thinner. This makes them more susceptible to agents that act on or through the skin. They have smaller fluid reserves and higher metabolic rates. Therefore, they are more vulnerable to dehydration from vomiting and diarrhea and suffer increased toxicity from a given exposure, such as to radioactive iodine (I\textsubscript{131}).

The use of biologic and chemical agents dates back to biblical times, although the threat from radiation and nuclear detonation is relatively new. Assyrians poisoned the wells of Kaffa in the 6th century BC. The Mongols catapulted bodies infected with bubonic plague over the walls of Kaffa in the 14th century. The British Army gave American Indians blankets taken from individuals infected with smallpox during Pontiac’s Rebellion in 1763. During World War I, the Germans effectively used chlorine and mustard agent against the advancing Allied armies. The Japanese killed hundreds to thousands of Chinese citizens with bubonic plague during World War II by spraying towns with fleas infected with Yersinia pestis. Saddam Hussein employed a mustard agent against the Iranians during the Iran-Iraq War in the 1980s.

The use of WMD has been predominantly by the military during times of conflict. In recent history, however, the use of these agents has taken an ominous turn. Nonaffiliated groups have begun using WMD directed at civilians to achieve political ends. The Bhagwan cult sprayed salad bars in Oregon with Salmonella in an attempt to influence an election in 1984. The Aum Shinrikyo used the nerve agent sarin in an unsuccessful 1994 assassination attempt on three judges in Matsumoto, Japan. This same group used sarin again in the 1995 Tokyo subway attack that killed 11 people. The United States experienced multiple anthrax hoaxes during 1997 and 1998, motivated by personal or political agendas. Terrorists initiated an actual anthrax attack using the U.S. mail in 2001 that resulted in 11 deaths. The perpetrator’s identity and motivation remain unknown. No one has yet used radiologic or nuclear devices in a successful terrorist attack, but at least one attempt has occurred. In addition, several highly radioactive sources have been stolen from U.S. medical facilities, and a Russian dissident, Alexander Litvinenko, was assassinated with a radiologic agent (polonium-210) in 2006.

Many agents are potential candidates for weaponization, and some represent a substantial risk (Box 194-1). Management strategies for patients exposed to WMD are frequently similar to strategies for hazardous materials exposure. However, several features associated with WMD make these events unique (Box 194-2). Additional knowledge and skills are required in the evaluation and treatment of WMD victims. These plans represent only one small part of an overall comprehensive emergency management strategy for all hazards (see Chapter 193). Names of departments, bureaus, and agencies that can assist with planning and response to WMD events are listed in Table 194-1.

NUCLEAR AND RADIOLOGIC DEVICES

Terrorists selecting radiation as a means to inflict casualties are unlikely to employ nuclear weapons. These devices are heavily guarded, difficult to move due to their size and weight, and easy to detect. Although Russia acknowledges that 50 to 100 of its 1-kiloton “suitcase” nuclear weapons are missing, the problems of purchasing, moving, and detonating these devices...
are formidable. Sabotage at nuclear power stations is possible, but given tight security, multiple safety systems, and thick concrete housings surrounding the reactors, the threat is probably low.

Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are thought to be the source of choice. These sources are plentiful. They do not detonate on their own and give no warning of their presence, unless dispersed by a conventional explosive (radiologic dispersal device). Thefts of radiotherapy sources have occurred in the United States. Accidental dispersion from a stolen hospital device. Thefts of radiotherapy sources have occurred in the United States. Accidental dispersion from a stolen hospital therapy source in Brazil resulted in the screening of 112,000 people to significant radiation. A total of 249 people were found to be exposed, 4 of whom ultimately died. Placement of such a device at an information kiosk in a crowded mall during a busy holiday shopping season would silently expose countless persons to significant radiation.

Ionizing radiation, regardless of its type, causes injury at the cellular level, usually by damaging DNA. Rapidly dividing cells are the most sensitive. Patients develop symptoms within hours to days, depending on the dose. Common syndromes associated with radiation exposure include dermal burns, bone marrow failure, and gastrointestinal dysfunction (e.g., vomiting and gastrointestinal bleeding) (see Chapter 144). A U.S. Department of Homeland Security task force developed an expert consensus document on medical treatment of radiologic casualties, and the results were subsequently published in the peer-reviewed literature.

A basic emergency department radiation protocol must address decontamination, triage, staff safety, personal protective equipment (PPE), and diagnostic procedures that emphasize size radiation monitoring. Victims presenting to the emergency department will suffer from three types of exposure: irradiation, internal contamination, and external contamination. Irradiated victims have been exposed to a beam of radiation, similar to someone undergoing a chest x-ray. They are not radioactive and pose no threat to emergency department personnel.

Contaminated patients are more challenging, and early involvement of the radiation safety officer is critical. This individual evaluates the degree of the victim’s contamination and monitors radioactivity levels throughout the decontamination process. Internally contaminated patients present a therapeutic challenge because they have radioactive material inside their bodies (e.g., lungs and gastrointestinal tract) or incorporated into their cells. They should be placed in an isolation room, where all secretions and bodily fluids can be collected. Various medications are available for administration to internally contaminated patients and can limit uptake or facilitate removal of certain radioactive elements. These medications include Radiogardase (Prussian blue) for cesium and thallium ingestions and diethyleneetriamine pentaacetic acid (DTPA) for plutonium exposure. Health care providers can receive assistance by calling the Radiation Emergency Assistance Center/Training Site (REAC/TS; http://orise.orau.gov/reacts) at 865-576-3131 (emergency number: 865-576-1005).

Externally contaminated victims have radioactive material on their skin or clothing and are decontaminated by removal of clothing and washing with soap and water. Washing by protected personnel must continue until monitoring by the radiation safety officer demonstrates the absence of radioactivity. If present, wounds are decontaminated first. After the wounds are covered with a sterile, waterproof dressing, the remaining skin is washed. Hospitals must be prepared to decontaminate patients because historical data suggest that up to 80% of patients do not receive this intervention before admission.

Decontamination before hospital entry is crucial because these individuals can expose caregivers to radiation and contaminate the entire hospital through the ventilation system. Removal of clothing and covering the head with a surgical cap can reduce contamination by 80% to permit stabilization in the decontamination unit, but complete decontamination should occur before exposure of unprotected staff if the patient’s medical condition permits.

Initial triage of radiation casualties is based on their overall pathologic condition, not on exposure. Even patients who have received a lethal dose of radiation do not die immediately as a consequence of the ionizing exposure. Therefore, a patient in acute distress from a myocardial infarction or urosepsis would be triaged ahead of a radiation victim with stable vital signs, regardless of the dose received. If a radiation casualty also suffers a severe injury or illness, immediate intervention is required. For example, most morbidity and mortality associated with a radiologic dispersion device are related to traumatic injuries from the explosion and not to radiation exposure.

In addition to patient contamination, the radiation safety officer is responsible for monitoring the exposure of hospital staff. All personnel involved in the care of contaminated patients should wear dosimeters, which measure the amount of radiation received by the wearer. The safety officer tracks the amount of radiation received by each staff member and can remove a health care worker from the area if the exposure is too high. Radiation monitoring is complex, and the radiation safety officer should be involved as early as possible. Hospitals should consider conducting disaster drills that include casualties suffering radiation injuries.

Although many radioactive elements are candidates for use in a terrorist attack, I\textsuperscript{131} and related isotopes deserve additional discussion because of heightened interest. I\textsuperscript{131} is found only after a nuclear detonation or in reactor fuel rods. Although not impossible, the probability that terrorists could tap either of these sources is very small. The use of I\textsuperscript{131} in a radiologic dispersal device is very unlikely due to its short half-life (8 days). Even if such a device could be made, it is extremely unlikely that the radiologic dispersal device could disperse sufficient radioactive material to pose an immediate health hazard. Given these facts, the probability that any significant exposure of the population (especially children) to I\textsuperscript{131} will occur is equally small. The large number of childhood thyroid cancers that occurred after the accident at the Chernobyl nuclear power plant was due mostly to situations that will not occur in the United States. These include delayed reporting of a breach in the reactor containment vessel preventing timely evacuation, failure to quarantine contaminated milk and vegetables, and significant iodine deficiency in the exposed children. Nonetheless, concern regarding treatment to prevent thyroid cancer after potential exposure to I\textsuperscript{131} remains. Current recommendations for treatment with potassium iodide, which blocks uptake of I\textsuperscript{131} by the thyroid, are listed in Table 194-2. Caveats for using this table include increasing the amount of potassium iodide for adolescents approaching 70 kg to the adult dose (130 mg) and monitoring thyroid-stimulating hormone and free T\textsubscript{4} levels in neonates when possible. Nonpregnant adults older than 40 years are unlikely to benefit from this intervention.

**BIOLOGIC WEAPONS**

By convention, biologic weapons are divided into three groups: bacteria, viruses, and toxins. A characteristic shared by these agents is their ability to be dispersed as an aerosol. Because this is the most effective means to expose a large population, aerosol dispersal is the most likely route that terrorists will use to deploy such weapons. Therefore, victims will have respiratory signs and symptoms. Dermal contact and ingestion are also potential pathways for exposure, and some agents are effective by these routes. People infected in the 2001 U.S. anthrax attack were inoculated via aerosol and dermal exposures. However, it is logistically more difficult to produce large casualty numbers using nonrespiratory portals of entry, so agents spread primarily by injection or through the gastrointestinal tract are less likely candidates for widespread deployment.

If the goal is to disrupt the economy or spread fear among the population, then almost any type of release will suffice, whether or not people actually die.

Patients exposed to biologic agents usually present with vague symptoms associated with flulike illnesses. Unless a biologic attack is announced or suspected, the emergency department staff may not realize they are treating victims. Indeed, it is not always possible to distinguish natural occurrences from engineered outbreaks of diseases. Therefore, personnel must be vigilant and at least consider the possibility of a bioweapon exposure when warning signs are present (Box 194-3). For example, large numbers of patients suddenly presenting with “the flu” not during flu season should cause concern. For these reasons, health surveillance will be paramount in identifying agents and potential sources. The emergency department must have a working relationship with local and state health departments as well as local law enforcement and stay apprised of CDC and Department of Homeland Security guidelines.

Several infectious agents with potential for use as biologic weapons can spread in a hospital environment. Examples include Ebola and smallpox. Hospitals need protocols for PPE and patient isolation to ensure a safe environment. Fortunately, such protocols are similar to those applied to other infectious diseases (Box 194-4). Implementation of such precautions is credited with halting the in-hospital spread of the Ebola virus in the 1995 Zaire outbreak. Decontamination
is not a priority unless the exposure is immediate. Standard (universal) precautions are generally sufficient, and special suits (e.g., levels A, B, and C) are unnecessary. Current assessment suggests that three biologic agents—anthrax, plague, and smallpox—represent the greatest threat.

Anthrax

*Bacillus anthracis*, a gram-positive spore-forming bacterium, is the causative agent of anthrax (“woolsorter’s disease”). The spores are extremely hardy and can survive for years in the environment. The disease is caused by exposure to the spores, not the bacilli in their vegetative state. It is normally a disease of sheep, cattle, and horses and is rarely seen in developed countries because of animal and human vaccination programs. Disease in humans can occur when spores are inhaled, ingested, or inoculated into the skin. The spores germinate into bacilli inside macrophages. The bacteria then produce disease by releasing toxins (e.g., protective antigen, edema factor, and lethal factor) that cause edema and cell death.

Russia and the United States have successfully developed anthrax into a biologic weapon. The effectiveness of this agent was clearly demonstrated by two events: an accidental release of spores from a biologic weapons facility in the former Soviet Union town of Sverdlovsk in 1979 and the intentional distribution of anthrax spores through the mail along the eastern seaboard of the United States in 2001. After the Sverdlovsk release, at least 66 people died downwind from the compound during the next several weeks, and animal cases of anthrax were reported 30 miles away. The ability of non-state-sponsored terrorist groups to develop anthrax as a weapon is uncertain. The Japanese organization Aum Shinrikyo made several attempts to disperse anthrax throughout Tokyo without success. The perpetrator of the U.S. anthrax attack remains uncertain. Whether the individual was not a foreign national, given that the strain of anthrax used in the attack (Ames strain) was developed by the U.S. government.

An inhalational anthrax attack is the most lethal form of the disease and is caused by inhaling spores into the lungs. The mortality rate was thought to exceed 90%. However, the data from the 2001 anthrax exposure call this figure into question (5 deaths in 11 cases). Although the actual mortality rate is unknown, it is probably in the 50% range. The minimum number of spores required to produce disease is unknown. The original number quoted in the literature, 10⁶ spores, appears high given recent experience. After phagocytosis by macrophages, the spores germinate and are transported to the tracheobronchial lymph nodes, where the bacteria multiply. Over 2 to 10 days, patients develop a flu-like illness, with malaise, fever, and non-productive cough. This initial phase can be delayed for more than 1 month in some patients. Within 24 to 48 hours, abrupt deterioration occurs, with overwhelming sepsis, shock, hemorrhagic mediastinitis, dyspnea, and stridor. A chest radiograph obtained at this time may show a widened mediastinum and hilar adenopathy, but typical radiographic findings are not dramatic and could be missed (Fig. 194-1). Computed tomography scanning of the chest is more sensitive and should be performed if the disease is suspected. Bloody pleural effusions can also occur, and examination of the lung fields frequently reveals consolidation. This can easily be confused with pneumonia (Fig. 194-2). Death usually results within 3 days, and 50% of patients develop hemorrhagic meningitis. Human-to-human transmission has not been reported with inhalational anthrax.

Initial diagnosis is generally made clinically, based on a flu-like or septic illness; a suspicious chest radiograph or computed tomography scan demonstrating hilar adenopathy, infiltrates, or pleural effusions; and a reason to consider anthrax in the first place (e.g., current outbreak or warning from authorities). Several clinical algorithms exist that attempt to separate patients with influenza from those with anthrax. Unfortunately, they are based on a handful of anthrax cases, and their usefulness remains in doubt. Sputum culture, Gram’s stain, and blood cultures are not helpful until late in the course of the disease. Tests to confirm the diagnosis of inhalational anthrax include the polymerase chain reaction for identification of anthrax markers in pleural fluid, serologic detection of immunoglobulin to protective antigen, and immunohistochemical testing of biopsy specimens.

In addition to inhalational anthrax, cutaneous anthrax can occur in any area where large numbers of spores are released, as was the case in the United States in 2001. This form of the disease occurs when spores are introduced into the skin, usually through open wounds or abrasions. The mortality rate is approximately 20% without treatment and 1% with treatment. Antibiotics do not affect the course of local disease but...
are used to prevent dissemination and death. After an incubation period of 1 to 5 days, a papule develops, progressing to form a large vesicle over the next several days. Severe edema occurs around the lesion and is associated with regional lymphadenitis. The lesions are not tender, and the patient may or may not be febrile (Fig. 194-3). In the next 2 or 3 weeks, either the eschar sloughs off and the illness is over or the organism disseminates and the patient dies. As with inhalational anthrax, the diagnosis is predominantly clinical. Confirmation is established by culturing of the lesion, punch biopsy, or serologic testing. A total of 11 cutaneous anthrax cases occurred in the United States after the 2001 attack.22

A few cases of gastrointestinal anthrax and oropharyngeal anthrax are also possible after a terrorist attack. These rare manifestations usually occur with the ingestion of insufficiently cooked, contaminated meat. The mortality rate is approximately 50%. After ingestion, the spores are transported to regional lymphatic tissue, where symptoms develop after a 2- to 5-day incubation period. Patients with oropharyngeal anthrax present with sore throat and neck swelling from cervical and submandibular lymphadenitis. The tonsils are also frequently involved, and symptoms are associated with fever and toxicity. Dysphagia and respiratory distress often follow. Gastrointestinal anthrax begins with nausea, vomiting, and fever associated with mesenteric lymphadenitis. Patients then experience severe abdominal pain, hematemesis, ascites, and bloody diarrhea and may present with an acute abdomen.

**Treatment**

Traditional treatment for anthrax infection has been penicillin. However, weapons-grade anthrax is probably resistant to penicillin (although this was not the case with the U.S. attack). Current treatment recommendations reflect this fact (Box 194-5). These consensus recommendations include fluoroquinolones and tetracycline for all children, regardless of age. Balancing the potential risks of such drugs against the consequences of infection by drug-resistant anthrax strains, the benefits justify the recommendations. Nontoxic victims with cutaneous anthrax can be treated as outpatients with oral ciprofloxacin or doxycycline for 7 to 10 days. Victims with inhalational, cutaneous, or gastrointestinal anthrax with toxicity should receive intravenous therapy with ciprofloxacin, doxycycline, or penicillin G. Treatment for 60 days or until patient receives three doses of vaccine is recommended.
Plague

Plague has been a human pathogen since antiquity. Many regions of the world, including Asia and India, are currently witnessing the third pandemic of plague, and this affliction is endemic in the western half of the United States. Plague is caused by *Yersinia pestis*, a gram-negative bacillus. It is normally a disease of rodents that is transmitted to humans through the bite of an infected flea or by inhalation. Three forms of the disease exist: pneumonic, bubonic, and septicemic plague. The bacteria do not form spores and die rapidly in the environment. However, they are viable for days in dry sputum, flea feces, and human remains. Dogs are relatively resistant to infection, but cats are highly susceptible and could become infected if exposed during the procedure. Organisms can be aspirated from the nodes for diagnosis, but incision and drainage is not recommended because the lymphadenitis resolves with antibiotic treatment, and practitioners could become infected if exposed during the procedure.

During the next week or more, the bacteria disseminate in approximately 50% of patients with bubonic plague. These victims develop septicemic plague or secondary pneumonic plague and die if untreated. Those with septicemic plague experience endotoxemia, shock, disseminated intravascular coagulation, and coma. If bacteremia does not occur, most victims recover. A small percentage of those infected by fleas develop septicemic plague without detectable buboes. Direct human-to-human transmission does not occur with bubonic or septicemic plague. However, both of these conditions can lead to secondary pneumonic plague, which is communicable.

Therefore, initial isolation (for the first 48 hours) is recommended for all patients with plague.

Differential Diagnosis

The preliminary diagnosis of plague is clinical. Few diseases other than plague cause fulminant gram-negative pneumonia associated with hemoptyisis in previously healthy individuals. The same can be said for diseases that cause lymphadenopathy, Cat-scratch disease, tularemia, and staphylococcal or streptococcal infections are all in the differential diagnosis. However, the extremely tender nature of the lymphadenopathy and the toxicity of the patient strongly suggest plague. Once the disease is suspected, Gram’s stain and culture of sputum, blood, cerebrospinal fluid, or lymph node aspirate are helpful. State health departments or the CDC can test specimens for the presence of the capsular antigen using direct fluorescent antibody staining. Polymerase chain reaction also holds promise. Unfortunately, all laboratory tests require several days to complete, so initial management decisions must be based on clinical findings.

Treatment

Antibiotic treatment is essentially the same for all three types of plague (Box 194-6). The same caveats for the use of fluoro-
TREATMENT FOR PLAGUE

BOX 194-6

Parenteral Therapy

Adults
- Streptomycin,* 1 g IM bid
- Gentamicin, 5–7 mg/kg once daily IM or IV
- Doxycycline, 100 mg IV bid
- Ciprofloxacin, 400 mg IV bid
- Chloramphenicol, 25 mg/kg IV qid

Children
- Streptomycin,* 15 mg/kg IM bid (max 2 g/day)
- Gentamicin, 2.5 mg/kg IM or IV tid
- Doxycycline, 2.2 mg/kg IV bid (max 200 mg/day)
- Ciprofloxacin, 15 mg/kg IV bid (max 800 mg/day)
- Chloramphenicol, 25 mg/kg IV qid

Pregnant women: Same as above but exclude streptomycin and chloramphenicol.

Oral Therapy

Adults
- Doxycycline, 100 mg bid
- Ciprofloxacin, 500 mg bid
- Chloramphenicol, 25 mg/kg qid

Children
- Doxycycline, 2.2 mg/kg bid (max 200 mg/day)
- Ciprofloxacin, 15 mg/kg bid (max 1 g/day)
- Chloramphenicol, 25 mg/kg qid

Pregnant women: Same as above but exclude chloramphenicol.

*Although streptomycin is recommended as first-line treatment, it may not be readily available.

quino... ceased 20 years ago. Given its high infectivity and lethality, this makes smallpox an excellent biologic weapon.

The variola virus is spread as an aerosol. It can survive for 24 hours, possibly 48 hours, in the environment. The occurrence of smallpox in hospital employees whose only exposure was handling laundry from infected people is testimony to its viability. Approximately 30% of exposed people become ill. One infected person has the potential to infect up to 20 other individuals. People are infectious from the time the rash first appears until the scabs fall off (1 or 2 weeks). Anyone exposed to smallpox must be quarantined and observed for 17 days to rule out infection.

The disease manifests clinically in several forms. Variola major and variola minor represent 90% of the cases. Variola major is the classic form—a more severe illness with a mortality rate of 30%. Variola minor is a milder form, with less toxicity, fewer pox, and a mortality rate of 1%. Two other forms of the disease, hemorrhagic and malignant (or flat) smallpox, are seen in 10% of cases; the mortality rate is greater than 90%. Patients with hemorrhagic smallpox develop symptoms earlier and become toxic quickly. Instead of pox, their rash is characterized by petechiae and hemorrhage. Death occurs in 5 or 6 days. Those with malignant smallpox have a similar course, but their rash is characterized by soft, flattened lesions that never progress to pustules. If they survive, the lesions resolve without forming scabs.

The infection begins when the virus is inhaled. After migrating to regional lymph nodes, the virus replicates for 3 or 4 days and then asymptomatically spreads to the spleen, bone marrow, other lymphoid tissue, and liver. A second viremia occurs 8 to 12 days later and is associated with fever, prostration, and headache. Mental status changes can occur. During this phase, which lasts 2 or 3 days, the virus localizes to the skin and pharyngeal mucosa. A maculopapular rash soon appears, which becomes vesicular and finally pustular. The rash first appears on the face and forearms, later spreading to the legs and trunk. All the lesions in any one area of the body are the same age (Fig. 194-5). During the next 8 to 14 days, the pustules crust over and separate from the skin, leaving pitted scars.

A clinical algorithm developed by the CDC can assist in assessing the probability that an individual has smallpox. It relies on three major and five minor criteria. The major criteria are a febrile prodrome, classic smallpox lesions, and lesions in the same stage of development. The minor criteria are centrifugal distribution of pustules; first lesions on the oral mucosa, face, or forearms; toxic appearance; slow evolution of lesions; and pustules on the palms and soles. A patient with all three major criteria is at high risk and should be isolated and reported...
to public health authorities and law enforcement agencies immediately. Patients with the febrile prodrome and either four minor criteria or one other major criteria are at moderate risk. Consultation with infectious disease and dermatology specialists should be sought and tests ordered to confirm variella. If smallpox cannot be ruled out after these interventions, the patient should be treated as high risk. If a patient does not have the febrile prodrome or has the prodrome but no other major criteria and has fewer than four minor criteria, the individual is at low risk for smallpox. These patients can be managed as clinically indicated.26

Differential Diagnosis

As with anthrax and plague, the initial diagnosis of smallpox is clinical. Other illnesses resembling smallpox include chickenpox, herpes simplex, and monkeypox. Unlike variola, the rash associated with chickenpox (varicella) is seen first on the trunk and then spreads to the extremities and face. In addition, the pustules are in different stages of evolution in any one area of the body. If the first case seen is hemorrhagic or malignant smallpox, the diagnosis will probably be missed until more typical cases present. To confirm the diagnosis, vesicular fluid or scabs were traditionally sent for electron microscopic examination. Polymerase chain reaction techniques appear promising for rapid viral identification, with sensitivities and specificities in the 98% range.27

Treatment

No effective therapy exists for victims infected with smallpox who become symptomatic. However, potential antiviral agents, such as cidofovir, show promise. In mice exposed to a lethal cowpox challenge, administration of an oral lipid produg of cidofovir in modest doses once a day for 5 days produced 100% survival.28 Vaccinia immunoglobulin (VIG) has no role in the treatment of active disease. Some practitioners suggest that most smallpox patients should be isolated at home or other nonhospital facilities because the virus spreads easily in a hospital environment and the disease is currently untreatable.8

The best strategy for containing the disease is vaccination of the susceptible population. Vaccinating an immunocompetent individual within 3 days of exposure will prevent or significantly ameliorate illness. Vaccination up to 7 days after exposure may prevent death. Complications from vaccination with vaccinia virus occur and can be fatal. Groups at risk for these adverse consequences include pregnant women and people with eczema, human immunodeficiency virus infection, and immunosuppressive conditions (e.g., malignancy, chronic steroid use, and hereditary immunodeficiencies). Given the seriousness of the disease, the current recommendation is to vaccinate these individuals and simultaneously administer 0.3 mg/kg of VIG intramuscularly (IM). For people who develop complications from the vaccine (e.g., progressive vaccinia, ocular autoinoculation, and eczema vaccinatum), the dose of VIG is 0.6 mg/kg IM and is divided over 24 to 36 hours. Ribavirin can be administered but is considered experimental. VIG is not indicated for vaccinia-associated encephalitis.

The smallpox vaccine supply situation has improved dramatically in the United States. The CDC has 100 million doses of the traditional smallpox vaccine (Dryvax). These vials can be diluted 5:1 to produce a total of 500 million doses without any decrement in the vaccine’s efficacy.29 In 2004, a British company delivered an additional 209 million doses of a second-generation vaccine derived from the same vaccinia virus used in Dryvax but grown in cell cultures. In addition, work is commencing on production of an improved modified vaccinia ankara vaccine. The virus used in the modified vaccinia ankara vaccine is so attenuated that it does not replicate in a human host. This may make it safe for administration to immunocompromised individuals.

CHEMICAL WEAPONS

Unlike victims of biologic weapons, casualties exposed to chemical agents manifest symptoms quickly, from immediately to a few hours after contamination.30 Therefore, surveillance and recognition are less problematic. The challenge is decontamination and treatment.

Terrorism with chemical weapons produces casualties similar to those seen in hazardous materials incidents, and medical management is comparable. However, the unique features of such events, including the volume of patients and the risk of hospital contamination, necessitate additional preparation. For example, the Tokyo subway attack using sarin in 1995 resulted in 11 deaths and more than 5000 patients converging on local emergency departments. Although the majority of these patients had subclinical exposure or psychological symptoms alone, the health care system was severely taxed. Secondary contamination by direct contact or vaporization occurred in ambulances and at the hospitals.3

Health care facilities must have protocols in place to deal with the eventuality of chemically contaminated patients (Box 194-7).31,32 Current recommendations for levels of PPE and types of decontamination facilities necessary in a hospital setting are inconclusive.33

The four basic classes of chemical agents are nerve, vesicant ( blistering), blood, and pulmonary (choking). Although all have potential for use as weapons, the nerve agents and vesicants are thought to represent the greatest threat.

Nerve Agents (Sarin, Tabun, Soman, and VX)

Nerve agents are organophosphates. They inhibit the enzyme acetylcholinesterase, blocking the degradation of acetylcholine at the postsynaptic membrane. Acetylcholine accumulates, resulting in overstimulation of muscarinic and nicotinic receptors. Symptoms are receptor dependent. Stimulation of muscarinic receptors produces miosis, salivation, rhinorrhea, lacrimation, bronchorrhea, bronchospasm, vomiting, and defecation. The major life threat associated with this syndrome is ventilatory compromise from profound bronchorrhea and bronchoconstriction. Stimulation of nicotinic receptors produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. Unlike typical organophosphates, exposure to nerve agents has not been associated with urination. In addition, bradycardia is rare, and miosis does not respond to systemic therapy.2

---

**BOX 194-7**

**EMERGENCY DEPARTMENT PREPAREDNESS FOR CHEMICAL WEAPONS OF MASS DESTRUCTION**

- Community-based hospital planning
- Personnel trained in recognition, mass casualty triage, and treatment
- Decontamination facility with protocols (runoff water, warm water, etc.)
- Personal protective equipment readily accessible and compliant with regulations
- Rapid access to antidotes, cyanide kits, and anticonvulsants
- Hospital incident management system in place
- Knowledge of how to access experts quickly
Nerve agents also cause direct central nervous system toxicity that manifests as seizures, coma, and apnea. In survivors, residual central nervous system effects manifest as psychological changes that can last 4 to 6 weeks. These manifestations are caused by chemical effects, not stress.

A preliminary diagnosis of nerve agent exposure is based on clinical findings. Important features include muscle fasciculations and miosis, which are sufficient to justify treatment pending further evaluation. Diagnosis is confirmed by measuring red blood cell cholinesterase levels. This test is not readily available, however, so treatment must begin before test results are known.

Terrorists are most likely to employ the nerve agents sarin (designated GB) and VX. Sarin exists as a liquid at room temperature but represents primarily a vapor threat because of its high volatility. Symptoms occur within seconds after inhaling vapor and peak at 5 minutes. There are no delayed effects; patients remaining asymptomatic 1 hour after possible exposure have not been contaminated. They can be sent home. VX is a thick liquid with low volatility. It represents a liquid threat only. Victims generally develop symptoms after skin exposure. The median lethal dose ($L_D^{50}$) for VX is 10 mg, a droplet slightly larger than a pinhead. Death from doses of this size occurs in less than 30 minutes. Delayed symptoms occur, so individuals must be observed for 18 hours before potential contamination can be ruled out.

Decontamination of victims exposed to sarin vapor requires only removal of clothing. People contaminated with VX or liquid sarin must have their clothing removed and then must be decontaminated using showers. When the level of exposure or the involved agent is uncertain, full decontamination is prudent. Responders caring for patients in the presence of liquid sarin exposure may require level A or B protective suits.

Treatment

The treatment of nerve agent victims depends on the form (liquid or vapor) and level of exposure (mild, moderate, or severe) (Box 194-8). Three drugs are the mainstay of treatment: atropine for the muscarinic effects (improves ventilation), pralidoxime chloride (2-PAM) for the nicotinic effects (reverses paralysis), and diazepam for the prevention and treatment of seizures (Box 194-9). The dose of atropine is titrated to the drying of respiratory secretions and not to heart rate or pupil size. If diazepam is unavailable, other benzodiazepines can be used. 2-PAM is most effective if administered within 4 to 6 hours of sarin exposure. After this period, the drug’s impact wanes due to “aging,” defined as the permanent attachment of sarin to the acetylcholinesterase enzyme. Hypertension can occur during 2-PAM administration and is controlled by intravenous phentolamine, 5 mg for adults and 1 mg in repeated doses for children.

An autoinjector kit (Mark I) approved by the FDA consists of two cartridges, one containing atropine (2 mg) and the other 2-PAM (600 mg). Mark I kits are available as part of civilian pharmaceutical caches strategically located throughout the United States. An autoinjector containing 10 mg of diazepam is also available. Doses should be adjusted for pediatric and elderly patients. Using the Mark I kits to treat these populations can be problematic because of difficulty in adjusting the dose. An alternate solution is to inject the medication into a sterile vial. The drug can then be re-aspirated in an appropriate amount for the patient’s weight or age and administered.\textsuperscript{14}

**Vesicants (Mustard)**

Vesicants (blistering agents) are chemical warfare agents that induce blister formation when contacting skin. Terrorists could use several of these compounds, but mustard is considered the chemical of choice. Mustard is a liquid at room temperature but has both liquid and vapor toxicity. Injury from mustard exposure occurs in 1 or 2 minutes, but symptoms do not develop for 4 to 8 hours. The exact mechanism is unknown, but the agent damages DNA, causing eventual cell death. Mustard has both local and systemic toxicity. Local effects occur from direct exposure to the skin, eyes, and airway. Systemic effects result from the impact of absorbed mustard on the bone marrow. Treatment is supportive and includes decontamination (to prevent secondary contamination) and airway maintenance. Although no specific antidote for mustard is currently available, a topical iodine preparation shows promise.

**Type and Degree of Nerve Agent Exposure**

**Vapor Exposure (Sarin)**

- **Mild:** Rhinorrhea and miosis
- **Moderate:** Mild symptoms plus increased secretions, wheezing/dyspnea, muscle weakness/fasciculations, or gastrointestinal effects
- **Severe:** Apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems

**Liquid Exposure (VX)**

- **Mild:** Localized sweating and fasciculations where a drop touches the skin; no miosis; may be delayed for 18 hours
- **Moderate:** Gastrointestinal effects; miosis uncommon; may be delayed for 18 hours
- **Severe:** Apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems; occurs in less than 30 min at or above $L_D^{50}$

**Treatment for Nerve Agent Exposure**

**Vapor**

- **Mild:** Observe for 1 hr; then release; no treatment
- **Moderate:** One or two Mark I kits IM or
  - Atropine, 2–4 mg IV, may repeat every 5–10 min as needed, and 2-PAM, 1 g IV over 30 min, may repeat every hour as needed
- **Severe:** Three Mark I kits IM and one diazepam autoinjector IM or
  - Atropine, 6 mg IV, may repeat 2 mg boluses IV every 5–10 min, and 2-PAM, 1 g IV over 30 min, repeat every hour for total of 3 g, and diazepam, 5 mg IV, may repeat as needed

**Liquid**

- **Mild:** One Mark I kit IM or
  - Atropine, 2 mg IV, and 2-PAM, 1 g IV over 30 min
- **Moderate:** Same as for vapor
- **Severe:** Same as for vapor

**Pediatric Doses**

- Atropine, 0.02 mg/kg IV
- 2-PAM, 15 mg/kg IV over 20–30 min
- Diazepam, 0.2–0.3 mg/kg IV

*Give atropine before attempting intubation. Otherwise, airway resistance will inhibit ventilation. Continue atropine until secretions are dry (usually ≤20 mg). In hypoxic patients, IV atropine has been reported to cause ventricular fibrillation, so consider using IM atropine.*
When applied within 1 hour after mustard exposure to the skin of guinea pigs, an iodine-tetraglycol solution reduced vesicle formation and signs of inflammation. Application more than 1 hour after exposure was not effective.

Eye damage from mustard exposure varies from conjunctivitis to corneal ulcer and perforation; however, only 1% of patients have permanent eye damage. Severe pain is frequently associated with mustard injury and causes significant blepharospasm. Irrigation is beneficial if performed within minutes of exposure but ineffective once symptoms occur. Standard treatment includes mydriatics, topical antibiotics, oral analgesics, and petroleum jelly applied to the lids to prevent adhesions. Topical steroids are indicated only within the first 24 hours.

The hallmark of mustard injury is skin blisters resembling second-degree burns. Within 4 to 8 hours of exposure, erythema and burning occur, followed by vesicle and bulla formation. Most vapor injuries do not involve the entire dermis, so wounds will not require skin grafting. If liquid exposure occurs to skin, full-thickness burns may result. The patient should be decontaminated by removing clothing and washing with water or a dilute bleach (1:10 hypochlorite) solution. Decontamination immediately after exposure prevents further injury to the patient, but delayed decontamination is indicated to protect staff. Treatment is supportive and includes standard burn wound management, analgesia, and tetanus prophylaxis. An important exception is fluid resuscitation. Fluid losses from mustard injury are much less than those associated with thermal burns. Therefore, standard burn formulas for fluid administration do not apply, and caution must be used to avoid overhydration.

The degree of airway injury after mustard exposure is dose dependent. Mild exposure causes irritation of the nose, sinuses, and pharynx and can be treated with cool, humidified mist. Moderate exposure extends to the larynx and upper trachea and may require treatment with oxygen, continuous positive airway pressure, or even intubation. Severe exposure involves the lungs, producing hemorrhagic necrosis of the bronchioles. Pulmonary edema is rare. Intubation is usually required, and patients may benefit from positive end-expiratory pressure and in-line bronchodilators. Steroids are of questionable benefit, and antibiotics should only be given for established infection.

Systemic toxicity from mustard is caused by bone marrow suppression. Absorbed mustard kills stem cells, causing the white blood cell count to decline after 3 to 5 days. Survival is rare if the white blood cell count falls below 200, which generally occurs when greater than 50% of the total body surface area is involved from exposure to liquid agent. Death after mustard exposure usually results from secondary infection.

BLOOD AGENTS (CYANIDE)

Blood agents such as cyanide bind to cytochromes within mitochondria and inhibit cellular oxygen use. Low-dose exposures result in tachypnea, headache, dizziness, vomiting, and anxiety. Symptoms subside when the patient is removed from the source. At higher doses, the symptoms progress to seizures, respiratory arrest, and asystole within minutes of exposure.

Victims should be removed from the area, have their clothing discarded, and receive oxygen. If no improvement occurs, the cyanide antidote is given. This has traditionally been the sequential administration of amyl nitrate, sodium nitrite, and sodium thiosulfate. However, the FDA has approved intravenous hydroxocobalamin for treatment of cyanide exposure. The initial dose is 5 mg and can be repeated if necessary.

PULMONARY AGENTS (PHOSGENE AND CHLORINE)

Pulmonary or choking agents cause an inflammatory reaction when they come into direct contact with the eyes and upper airway. They can be life-threatening if inhaled. No specific antidote exists. Treatment is mainly supportive and consists of removing the patient from the source, decontamination, airway maintenance, bronchodilator administration, and eye irrigation.

PART VII

The Practice of Emergency Medicine
PERSPECTIVE

Medicine is an empirical science based on the experiences and insights of past and contemporary practitioners. Because the clinical experience of an individual physician is a small fraction of the experience of the medical profession as a whole, the advancement of medical science depends on physicians’ abilities to assemble, organize, and disseminate information in order to learn from the experience of others.

The Medical Literature

During the past several decades, medical literature has exploded. Thirty years ago, physicians could understand most medical publications. Currently, reports frequently use sophisticated statistical analyses that are unfamiliar to most clinicians. Emergency physicians and other practitioners are increasingly aware that the quality of the research reported must be evaluated before the results can be considered valid and clinical practice altered. Also, the results of quality research may not be applicable if the population studied differs greatly from the patient population in the emergency physician’s clinical practice. Even a clinician who possesses the analytical skills necessary to understand the modern medical literature will find it difficult to remain current, given the rate at which medical studies relevant to emergency medicine are published. Thus, the emergency physician must have a plan to identify, select, and read high-quality, relevant articles. Furthermore, the emergency physician must understand a number of principles to be able to analyze published studies critically.

The first step toward achieving these goals is to identify a small number of journals on which to focus. Most high-quality studies relevant to emergency medicine are published in fewer than a dozen journals. Once a list of 6 to 12 journals is compiled, back issues can be skimmed to determine the average number of relevant articles in each issue. Those journals that publish the highest number of articles directly relevant to an emergency physician’s clinical practice should then be selected. An emergency physician in full-time clinical practice should probably focus on 2 to 6 journals per month. Regular pamphlet or audiotape updates reviewing recent literature relevant to emergency medicine can be purchased and used as a supplement to journal review. Articles should be pulled and read in full, however, before results are accepted and clinical practice is altered.

Possible articles should then be screened to evaluate the relevance of the study question and population and to determine whether the methodology is of sufficient quality to warrant reading the article in more detail. Quality and clinical relevance vary greatly in the peer-reviewed literature. Only articles that meet high standards for methodologic quality should be read in detail. The emergency physician must learn to differentiate high-quality studies from poor-quality studies with unreliable results. Practitioners who understand the concepts presented in this chapter will have the basic foundation to differentiate good from poor studies and to focus their reading on those studies most likely to yield results that warrant a change in clinical practice. Additional guidance can be obtained from the Journal of the American Medical Association’s Users’ Guides to the Medical Literature series (http://www.cche.net/usersguides/main.asp).

A steadily increasing amount of attention is being paid to the importance of rigorous methodology in the design and execution of clinical trials. A poorly designed statistical analysis can yield misleading results, but a trial is more likely to be weakened by a poorly chosen question, an inappropriate study population, or other methodologic errors that bias the results. Thus, although some degree of statistical literacy is important, the practitioner must also understand nonstatistical issues in the design and analysis of clinical studies.

TYPES OF CLINICAL STUDIES

Studies can be divided into two categories, cross-sectional and longitudinal (cohort), based on when the measurements are made on the study population. In a cross-sectional study, data are obtained from a population of patients at a single point in time, whereas in a longitudinal study, data are obtained from a population of patients over a period of time.

Cross-Sectional Studies

Many epidemiologic studies are cross-sectional. Although a cross-sectional study cannot prove a causal relationship between a risk factor or treatment and an outcome, strong associations between identified variables in cross-sectional studies are suggestive of such effects. Many important observations can only be made using cross-sectional studies because, for practical and ethical reasons, some variables cannot be artificially manipulated to determine...
their effect on patient outcome. Furthermore, the effect may be so delayed that a longitudinal study is impractical. An example is a study examining the association between cigarette use and lung cancer. It would be unethical to expose a nonsmoking population to the effects of cigarettes, and even if one were to identify a population that would voluntarily use cigarettes, it would be impractical to observe subjects long enough for malignancies from cigarette smoking to appear. However, a cross-sectional study of self-reported cigarette use and the diagnosis of lung cancer that examines a population of subjects at a single point in time can easily demonstrate an association.

Longitudinal Studies

In a longitudinal, or cohort, study, a population of patients is enrolled in the study and measurements are made over a period of time. Longitudinal studies can be observational, if no intervention is made, or they can be interventional.

Longitudinal Observational Studies

In a longitudinal observational study, data are collected from a group, or cohort, of patients over time, but no intervention is made. A longitudinal observational study can be either prospective or retrospective. In a prospective observational study, patients who meet specific eligibility criteria are identified, and data are prospectively gathered over time. Prospective observational studies are valuable for defining the course of a particular disease treated with standard therapies and for identifying subgroups of patients with differing prognoses. If an association is noted between treatment and outcome in a prospective observational study, the association should be verified in a prospective interventional randomized clinical trial.

Although an observational study cannot prove a causal relationship, associations between initial patient characteristics or specific treatments and subsequent outcome can be detected. Such associations can be measured more accurately in a prospective longitudinal study than in a cross-sectional study because both the original patient characteristics and the subsequent outcome are determined prospectively. When these are determined prospectively, any associations observed are more likely to be true and not a result of bias.

In a retrospective observational study, medical records of patients with certain initial characteristics who are treated over time are reviewed and data abstracted. As with all retrospective studies, retrospective observational studies are subject to recording bias, problems with missing information, and other methodologic limitations. Because retrospective studies have these additional sources of bias and limitations, prospective studies provide higher quality evidence than retrospective studies. Prospective studies, however, are usually more difficult and time-consuming to perform.

Longitudinal Interventional Studies (Clinical Trials)

Interventional studies, which must be prospective, involve the artificial manipulation of a patient’s therapy to determine the effect of an investigational treatment. An interventional study can be controlled or uncontrolled, and, if controlled, it should be randomized.

In an uncontrolled interventional study, all patients who meet defined eligibility requirements are given the investigational therapy, and their outcomes are determined. Although such studies are useful for defining the rate of successful therapy in a well-defined population of subjects, the lack of a control group makes it difficult to estimate the relative effectiveness of the new therapy compared with another therapy. Previous experience with the standard treatment, in the form of a historical control group, can be used for comparison to the group receiving the new therapy. The use of such historical control groups is unreliable and often leads to an overestimate of the relative effectiveness of the new investigational therapy.

Medical care generally is becoming more effective, and thus the results of modern studies tend to yield better patient outcomes, even if the investigational treatment has no inherent advantage over the therapy received by the historical control patients.

In a controlled clinical trial, some patients are given the new investigational treatment, and some patients (control group) are given a standard treatment. The purpose of the control group is to define the effectiveness of the standard therapy in a group of patients as similar as possible to the group receiving the investigational therapy. To obtain two groups of patients who are nearly identical with respect to all characteristics that might influence the outcome of their disease, it is important that no external or subjective factors influence the assignment of treatment. Each patient must have the same chance of receiving each therapy. For this reason, assignment to control or therapy groups should be randomized.

It is extremely important that control patients be given a therapy that is at least as effective as the best currently available treatment. It is unethical for a control group to receive an inferior treatment simply to demonstrate that a new treatment has some effectiveness.

In general, longitudinal interventional studies provide the highest quality evidence, although this is controversial.

### RANDOMIZED LONGITUDINAL INTERVENTIONAL STUDY (CLINICAL TRIAL)

The steps in a randomized clinical trial assume that a worthwhile research question has been defined (Fig. 195-1). No matter how well designed the study, if the research question is not well-defined and not clinically useful, the intended audience will not find the study’s results valuable. The research question must also be prospectively defined; it is not appropriate to gather data and then devise a research question to fit the data. A good research question clearly defines four elements: (1) patient population and problem to be studied, (2) intervention to be applied to the treatment group, (3) comparison (control) intervention, and (4) outcome of interest.

Even if these four elements are well-defined, the research question must still have relevance for the emergency physician. For example, a study that compares oral and parenteral antibiotics (treatment and comparison interventions) for the prevention of meningitis (outcome) in well-appearing febrile children with occult bacteremia confirmed by positive blood culture (patient population) is less useful to the emergency physician than a similar study including all well-appearing febrile children because results of blood cultures are not typically available in the emergency department.

### Step 1: Definition of Patient Population

Assuming an appropriate research question has been selected, the first step is to define the patient population to be studied. The original patient population defined in the research question may be modified slightly by practical factors in study design. For example, although an investigator may want to study all asthmatic patients presenting to the emergency department, it may only be practical to study those presenting when investigators are available (convenience sample). Explicit
Step 1: Definition of the patient population
Step 2: Recruitment and enrollment of patients
Step 3: Randomization
Step 4: Measurement of baseline characteristics
Step 5: Treatment or intervention
Step 6: Collection of data on outcome
Step 7: Data management
Step 8: Statistical analysis
Step 9: Presentation and publication of results

Problem 1: Heterogeneous population (confounding variables), poorly chosen inclusion criteria
Solution 1: Population defined in terms of emergency department presentation, confounding characteristics considered in definition of population

Problem 2: Bias in recruitment, self-selection by potential subjects
Solution 2: Consecutive enrollment, records of nonenrolled but eligible patients

Problem 3: Imbalance of important confounding characteristics, inadequate blinding
Solution 3: Effective randomization and blinding, stratified randomization

Problem 4: Imbalance of confounding characteristics
Solution 4: Planned prospective measurement of important confounding characteristics

Problem 5: Unequal compliance or attrition
Solution 5: Intention-to-treat analysis of final data, measurement of compliance, procedures to encourage compliance

Problem 6: Subjects lost to follow-up, poorly defined outcomes
Solution 6: Multistep plans to obtain follow-up data, unambiguous definitions of treatment outcome

Problem 7: Data entry errors, data reduction errors or bias
Solution 7: Data verification, double data entry, value-limited data entry, appropriate forms design

Problem 8: Type I and type II errors, ill-advised comparisons or subgroup analysis, covariate imbalance
Solution 8: Small number of comparisons, planning of analysis, adequate sample size, multivariate modeling

Problem 9: Overextrapolation of results, failure to recognize limitations of or biases in results
Solution 9: Peer review, replication of results by other investigators, educated readership

Figure 195-1. Implementation and analysis of a prospective randomized, controlled clinical trial.

Inclusion and exclusion criteria must be defined before enrolling any patients, and these criteria must be uniformly applied in determining which patients are eligible to participate in the study. For the study to be most applicable to emergency medicine, the population should be defined in terms of clinical characteristics that are observable in the emergency department. On the other hand, groups of patients defined by their clinical characteristics in the emergency department are highly heterogeneous. Some patients in the population may have more severe disease than other patients or may have a completely different cause for their symptoms.

When reading a study, one should look to see that the patient population is well-defined and reasonably comparable to one’s own patient population. If important segments of the population are excluded (e.g., those with severe disease), the study results are not applicable to this subgroup. Researchers should not generalize their conclusions to patients not included in their study population.

**Step 2: Recruitment and Enrollment of Patients**

Once a patient population is defined, the next step is to recruit patients for enrollment in the study. To the extent possible, all patients meeting the predefined eligibility requirements for the study should be enrolled. The method of recruitment and enrollment should ensure that there is no systematic tendency to exclude a subgroup of patients from the study who meet the inclusion criteria. If such a selection bias exists, it will make the results of the study inapplicable to the types of patients that were excluded. For example, if a study of head trauma patients specifies that informed consent must be obtained from the patient within the first half hour of presentation to the emergency department, there will be a systematic tendency to exclude patients with head trauma severe enough to result in an altered level of consciousness.

Even in a study that is appropriately designed, patients may self-select, resulting in selection bias. For example, patients of low socioeconomic status may be less likely than patients of high socioeconomic status to give consent for participation in clinical studies. Thus, although the disease may affect people in all socioeconomic strata, the study results may apply only to patients of high socioeconomic status similar to those who participated in the study.

To minimize selection bias, studies should aim to achieve consecutive enrollment of all patients who meet inclusion criteria. Furthermore, patients who meet eligibility criteria but are not subsequently enrolled should be counted to allow an estimation of the possible extent of any selection bias that might exist. When reading a study, one should look for information on eligible patients who were not enrolled. A significant number of such patients may indicate selection bias. Researchers should explain why these patients were missed and should justify the validity of their results despite missed patients by showing, for example, that demographics and disease characteristics of missed patients were similar to those of enrolled patients.

**Step 3: Randomization**

The third step in conducting a clinical trial is to randomize enrolled patients to the different treatments being compared.
The purpose of this randomized allocation is to create two groups of patients who, other than receiving different treatments, are as nearly identical as possible.\(^\text{11}\) Stratified randomization can be used to ensure that important confounding factors are equally distributed in the control and test groups.\(^\text{11}\) In a stratified randomization, patients with the stratifying characteristic are randomized independently of those without the characteristic. For example, in a study of therapy for closed head injury, patients with severe closed head injury as defined by a low Glasgow Coma Scale score could be randomized independently of those patients with a higher Glasgow Coma Scale score. This would help ensure that the control and test groups have equal fractions of patients with severe and mild closed head injury.

Whenever possible, both the patient and the treating physician should be “blinded” (double blinding) to the therapy given.\(^\text{11}\) Such blinding is important to ensure that both the patient and the investigating physician can make unbiased estimates of endpoints, including the occurrence of undesirable side effects. Recently, increasing importance has been placed on subjective outcomes, such as quality-of-life assessments made by the patient. Blinding is especially important to ensure that the patients’ expectations regarding the effect of the new therapy do not influence their assessment of this type of outcome.

The quality of the randomization in a controlled clinical trial is important because studies that are inadequately randomized are more likely to “find” a positive treatment effect.\(^\text{16}\) Similarly, studies in which blinding is inadequate, so that the patient or the treating physician might be able to determine the treatment that the patient actually receives, are more likely to yield false-positive results.\(^\text{15}\) When reviewing a clinical trial, one should look for truly random treatment assignment and adequate blinding procedures. For example, in a trial in which patients are enrolled if determined to be sufficiently “stable” by the physician and assignment to therapy or control is alternated, a physician with the bias that the therapy is not efficacious may avoid enrolling a patient by deeming the patient unstable if the physician knows that the next patient will be assigned to the treatment group. A better method of randomization would be assignment by a computerized randomization program, such that no pattern of assignment can be discerned by the enrolling personnel.

**Step 4: Measurement of Baseline Characteristics**

The fourth step is to measure the characteristics of patients enrolled in the study before therapy. The purpose of these baseline measurements is to detect imbalance between the control and test groups in characteristics that might influence each patient’s chance for a successful outcome. Factors that might influence patient outcome and that are not controlled by the investigators are termed confounding variables. For example, the initial cardiac rhythm is a confounding variable in a study that compares different treatments for out-of-hospital cardiac arrest. If one group includes more patients in ventricular fibrillation and the other group has more patients in asystole, the intervention given to the first group will appear to be more efficacious. The influence of confounding characteristics must be anticipated, and those characteristics should be prospectively measured for all patients enrolled in the study. Subgroups of the overall patient population often have specific confounding characteristics (see Fig. 195-1). If a clinically significant difference in outcome is ultimately detected between the two treatment groups, the baseline characteristics of the treatment groups should be compared to ensure that the observed difference in outcome did not occur because the two patient groups were not initially equivalent.\(^\text{11}\) When reading a study, one should look to see that important confounders were measured and that they did not differ significantly between the groups studied.

**Step 5: Treatment or Intervention**

The next step is to administer the experimental treatment to the test group and the control treatment to the control group. Although the control and test patients should be nearly identical in their underlying characteristics, the two groups often have unequal compliance with therapy. For example, in a placebo-controlled study of an oral medication, patients taking the active drug may find that it causes gastrointestinal discomfort, whereas those taking the placebo treatment might not experience such an effect. Therefore, patients taking the active agent may be less compliant with therapy. Unequal compliance complicates the interpretation of the outcome data.

**Step 6: Collection of Data on Outcome**

The sixth step is to determine the outcome of each patient. Definitions of treatment success and treatment failure must be explicitly defined before any data are collected. Sometimes a trial is initially designed to investigate the effects of therapy on one outcome, but during data analysis investigators notice an apparently significant effect on a different outcome. Such a serendipitous finding may be true but can also result from chance because there are generally many such possible findings, and the study was not originally designed to investigate each of these possible outcomes. Such findings can be reported as interesting and warranting further investigation but should not be reported as reliable conclusions.

A difficulty with the collection of outcome data arises if too many subjects are lost to follow-up. This is more likely to occur in studies that evaluate the long-term effects of therapy. Patients who are lost to follow-up may have different characteristics than those patients who keep their follow-up appointments. For this reason, lack of complete follow-up in the study population can bias the results of the study.

Ensuring high rates of follow-up in studies of outpatient therapy is notoriously difficult. One approach is to create a multistep plan to obtain follow-up, with specific procedures to be followed if patients miss their first, second, or even third follow-up appointment. When reading a study, one should look at the percentage of patients lost to follow-up and look for a systematic effort to maintain good follow-up.

**Step 7: Data Management**

Once patients have been enrolled and have had their baseline characteristics measured, treatments administered, and outcomes determined, all this information must be organized and stored in a format that allows analysis of the data. Data should be collected on a form that limits and organizes the information. In general, information to be recorded on the data form should be highly structured, with categorical variables limited to a small number of possibilities and with very little (or no) unformatted “fill-in-the-blank” information requested. Such structure is required if the resulting data are to be analyzed statistically.

Errors may be introduced when data are entered into the database from data sheets. Bias can be introduced if certain types of data (e.g., written phrases in a patient questionnaire) must be reduced to a smaller number of categoric responses during the data entry procedure. Databases should be designed
to ensure that the data listed are reasonable. For example, the electronic database should not allow entry of patient temperatures that are incompatible with life or negative blood pressures. When reviewing a study, one should look for data categorizations that are clear and clinically useful. For example, a study of postresuscitation neurologic outcomes would be most useful to the emergency physician if patients were categorized as “normal,” “mildly impaired,” “severely impaired,” or “dead” versus the more vague terms “good” or “poor” or by the results of a detailed neuropsychological battery of tests.

**Step 8: Statistical Analysis**

The next step is to analyze the data. Careful planning of the statistical analysis to be performed is required to minimize the chance of erroneous conclusions. Only a small number of comparisons should be made, and the study should be designed to have an adequate sample size to reliably detect a clinically important treatment effect. The comparisons to be conducted must be defined prospectively, as well as any specific subgroups of patients that will be considered separately. Any imbalance in confounding baseline characteristics should be accounted for in the statistical analysis. Specific statistical tests are discussed later.

**Step 9: Presentation and Publication of Results**

Once the clinical trial data have been statistically analyzed, conclusions can be drawn from the results of the study. During the preparation of a manuscript describing the study and its conclusions, the investigators must be careful not to overextrapolate the results. Care must be taken to explain limitations in the study design and to enumerate factors that might bias the results of the study or at least limit its applicability to different patient populations. One purpose of the peer review process is to ensure that appropriate care is taken in interpreting the clinical trial results.

The enthusiasm of most investigators and clinicians for the results of a clinical trial is partly determined by the direction of the results. For example, a trial that shows a highly effective new therapy for a serious disease is interesting and exciting. On the contrary, a trial that shows that a previously unstudied therapy has no advantage over the currently accepted treatment may be less interesting. Because positive results are inherently more interesting, it is commonly believed that clinical trials yielding positive results are more likely to be published than those with negative results. This effect is termed publication bias.

However, studies have shown that trials with negative results may be less likely to be submitted for publication but, once submitted, are as likely to be published as trials with positive results. Thus, publication bias may be the result of a file drawer problem, meaning that study results that are negative sometimes end up in the file drawer instead of in manuscripts submitted for publication.

Publication bias and the file drawer problem are serious threats to the validity of the medical literature taken as a whole. If negative trials are selectively excluded from the medical literature, an ineffective treatment may appear to be at least partially effective because those (possibly poorly designed) studies that show some positive treatment effect are selectively submitted for publication. Meta-analyses or systematic reviews often utilize only published research. It may be unethical to subject patients to the risks and discomforts of participation in a clinical study and not publish the results, especially if participation did not result in any direct benefit to the patient.

Publication bias and other sources of bias can be especially problematic in pharmaceutical or commercially sponsored clinical research. Commercial studies are less likely to report unfavorable conclusions. Data from industry-sponsored research may go unpublished or may be difficult to obtain for subsequent review. When reading a clinical trial, one should determine what agency or company funded the research and consider what biases, if any, might have been introduced.

### DATA ANALYSIS

**Classic Hypothesis Testing**

Data from clinical trials are usually analyzed using $P$ values and classical hypothesis testing. In classical hypothesis testing, two hypotheses that might be supported by the data are considered. The first, called the null hypothesis, states that no difference exists between the groups being compared with respect to the measured outcome of interest. For example, in a study examining the use of a new sympathomimetic agent for blood pressure support in patients with sepsis, the null hypothesis might be that there is no difference between the average systolic blood pressure achieved with the test agent and that achieved with the control agent. The alternative hypothesis states that the groups being compared are different.

In this example study, the alternative hypothesis might be that the test agent results in a 10 mm Hg greater average systolic blood pressure than the control agent. The magnitude of the difference between the two groups defined by the alternative hypothesis is called the treatment effect (Tables 195-1 and 195-2).

<table>
<thead>
<tr>
<th>Table 195-1</th>
<th>Steps in Classical Hypothesis Testing</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>STEP</strong></td>
<td><strong>DESCRIPTION</strong></td>
</tr>
<tr>
<td>Define the null hypothesis</td>
<td>There is no difference between the groups being compared. For example, in a clinical trial the null hypothesis might be that the response rate in the treatment group is equal to that in the control group.</td>
</tr>
<tr>
<td>Define the alternative hypothesis</td>
<td>The alternative hypothesis might be that the response hypothesis rate in the treatment group is greater than that in the control group by a given amount.</td>
</tr>
<tr>
<td>Calculate a $P$ value</td>
<td>This calculation assumes that the null hypothesis is true. One determines the probability of obtaining the results found in the data or other results even more inconsistent with the null hypothesis. This probability is the $P$ value.</td>
</tr>
<tr>
<td>Accept or reject the null hypothesis</td>
<td>If the probability of observing the actual data, or more extreme results, under the null hypothesis is small ($P &lt; \alpha$), then we should doubt that hypothesis. The idea is that if the probability under the null hypothesis of observing the actual results is very small, then there is a conflict between the null hypothesis and the observed data, and we should conclude that the null hypothesis is not true.</td>
</tr>
<tr>
<td>Accept the alternative hypothesis</td>
<td>If we reject the null hypothesis, we accept the alternative hypothesis by default.</td>
</tr>
</tbody>
</table>
The treatment effect defined by the alternative hypothesis must be set before data are collected. The treatment effect should be large enough to be clinically important but small enough such that showing no difference between the groups rules out any clinically important treatment effect. In an interventional study, the difference defined is ideally the minimum treatment effect thought to be clinically significant (i.e., that which would lead to a change in clinical practice). Sometimes a larger treatment effect is defined because designing a study to reliably detect the smallest clinically significant treatment effect would require too large a sample size. When evaluating the results of a clinical trial, one should look for the size of the treatment effect that the trial was designed to detect.

Once the null and alternative hypotheses are defined, the null hypothesis is "tested" to determine which hypothesis (null or alternative) will be accepted as true. The process of testing the null hypothesis consists of calculating the probability of obtaining the observed results, or results that are even more inconsistent with the null hypothesis, assuming the null hypothesis is true. This probability is the $P$ value. If the $P$ value is less than some predefined value, denoted alpha ($\alpha$; usually 5% or .05), the null hypothesis is rejected as false, and the alternative hypothesis is accepted as true. In other words, if the null hypothesis were true, the probability of obtaining data like that obtained or even more extreme results by chance alone is less than alpha.

### Type I Errors

A type I error occurs when the investigator concludes that a difference has been demonstrated between two groups when no such difference exists. It is a type of false positive. When data are analyzed using $P$ values, a type I error occurs when a statistically significant $P$ value is obtained but there is actually no underlying difference between the groups being compared. Because the $P$ value is the probability of obtaining results equal to or more extreme than those actually observed, assuming there is actually no difference between the groups being compared, the risk of a type I error is equal to alpha, the maximum $P$ value considered statistically significant, when the groups are fundamentally the same.

### Type II Errors, Power, and Sample Size

A type II error occurs when a difference exists between the two groups and that difference is as great as that defined by the alternative hypothesis, but when a nonsignificant $P$ value is obtained. In other words, there really is a difference between the two groups, but the trial failed to demonstrate this difference. A type II error is a type of false negative and is commonly denoted beta ($\beta$).

The $power$ of a trial is the probability of detecting a treatment effect of a given size, if one truly exists. Studies are usually designed to have a power of .80 or greater. Because the power of the trial is the chance of finding a true treatment effect, the quantity $(1 - \beta)$ is the chance of missing a true treatment effect (i.e., risk of committing a type II error). The value of $(1 - \beta)$, or the power, and the magnitude of the treatment effect the clinical trial is designed to detect (defined by the alternative hypothesis) determine the sample size required for the study.

The smaller the size of the treatment effect the study is designed to detect, the larger the required sample size will be for a given value of alpha (the maximum significant $P$ value) and for a given power. For any given treatment effect, a smaller maximum significant $P$ value or a larger power will also require a larger sample size. Surprisingly, clinical studies are often published with negative results even though the studies did not have a sample size sufficient to detect reliably a clinically significant treatment effect.

When reading a study, one should look for a statement about the power of the study. Generally, a power of .80 or greater is desirable. The treatment difference tested should not be too large, such that smaller clinically important treatment differences may still exist even after a "negative" result. Power and sample size should be estimated before beginning the study; a "post hoc power analysis" after the data have been collected is not recommended.

### Statistical Tests

Depending on the characteristics of the data being analyzed, different statistical tests are used to determine the $P$ value (Table 195-3). Student’s $t$-test and Wilcoxon rank sum test are used to compare continuous variables (e.g., serum glucose level and respiratory rate) between two groups of patients. If there are three or more groups of patients, one-way analysis of variance (ANOVA) and the Kruskal-Wallis test are used to compare continuous variables between the groups. The chi-square test and Fisher’s exact test are used to detect associations between treatment and outcome when both the treatment and the outcome are categoric variables (e.g., placebo vs. active drug, lived vs. died, and admitted vs. discharged).
Student’s $t$-test and one-way ANOVA are examples of parametric statistical tests. Parametric tests make assumptions about the underlying distribution of continuous variables. Both the Student’s $t$-test and ANOVA assume that the data are normally distributed (i.e., distributed in a bell-shaped curve around the central mean) and that the different groups yield data that have equal variance.

When the data to be analyzed are not normally distributed, the $P$ value should be obtained using a nonparametric test. 

Nonparametric tests are distribution free in that they do not rely on the data to have any particular underlying distribution. The nonparametric alternative to a $t$-test for unpaired samples is the Mann-Whitney test, or Wilcoxon rank sum test. For a statistical comparison of paired measurements, the Wilcoxon signed rank test can be used. The nonparametric alternative to one-way ANOVA is the Kruskal-Wallis test. The $t$-test may be used inappropiately when the data are unlikely to be normally distributed. If it is unclear whether the data are normally distributed, it is preferable to use the nonparametric test.

Confidence Intervals

Often, the primary goal of a clinical trial is not simply to obtain a “yes-no” answer to the question of whether or not a treatment has any efficacy at all but, rather, to estimate the magnitude of the treatment effect. This goal of measuring the effect of the treatment arises if another treatment is known to be effective. On the other hand, if no effective treatment is available, a new therapy may be adopted even if the study shows only the possibility of effectiveness.

When the primary goal of a study is to measure or estimate a treatment effect, the results should be reported using confidence intervals. In general, a confidence interval is a range of treatment effects within which the true treatment effect falls with a given degree of certainty. For example, a 95% confidence interval will contain, within its limits, the true size of the treatment effect 95% of the time. Confidence intervals are easily calculated for most data. Advanced statistical methods may be required to report confidence intervals for data with non-straightforward (e.g., normal or binomial) distributions.

Situations may arise in which a $P$ value and confidence interval can lead to different qualitative interpretations of the same clinical trial results. Suppose one is studying a treatment for a disease that has no known effective therapy. If the 95% confidence interval for the treatment effect ranges from $-2$ to 30%, where the treatment effect is measured as the change in the absolute percentage of patients with a good outcome, many clinicians would interpret this as showing that the therapy may have little benefit, it has the possibility of having significant benefit (improving the outcome for up to 30% of patients). Thus, many clinicians would adopt the therapy as appropriate, given the lack of an effective alternative. If classical hypothesis testing had been used to analyze the same data, a nonsignificant $P$ value would have been obtained. Many clinicians would then interpret the study as failing to show efficacy and conclude that the therapy was not appropriate for clinical use.

When reading a study, one should look beyond the $P$ values to the size of the treatment effect found and the width of the confidence intervals. If $P$ is reported as significant (usually $<.05$), one should make sure that the difference is clinically significant. For example, a difference in reduction of temperatures by 0.5°C between two antipyretics may not be clinically significant but would be statistically significant in a sufficiently large study. Issues such as cost, palatability, and adverse effects are likely to be more important in choosing between the two antipyretics. If $P$ is reported as not significant (usually $>.05$), the practitioner should ensure that the confidence interval is not so wide that a clinically important treatment effect is still possible, as in the previous example.

Multiple Comparisons

Whenever two groups of patients are compared statistically, even if they are fundamentally identical, a statistically significant $P$ value can be obtained by chance. If the maximum significant $P$ value (alpha) is .05, there is a 5% chance that a statistically significant $P$ value will be obtained when no true difference exists between the two patient populations. This risk of a false-positive $P$ value occurs each time a statistical test is performed. When multiple comparisons are performed, whether they are “pairwise comparisons” of more than two groups of patients or the comparison of many different characteristics between two groups of patients, the risk of at least one false-positive $P$ value is increased because the risk associated with each test is incurred multiple times (Table 195-4). For a small number of tests, the overall risk of at least one type I error is roughly equal to the maximum significant $P$ value used for each individual test multiplied by the total number of tests performed. This rough equality is the basis for the Bonferroni correction.

The Bonferroni correction is a method for reducing the overall type I error risk for the whole study by reducing the maximum $P$ value used for each of the individual statistical tests ("test-
subgroups or appropriate for more than two study groups. Therefore, the use of statistical methods accounting for multiple comparisons are statistically significant. When reviewing positive multiple comparison, such interim analyses must be planned and the trial can be terminated early. Because this is a type of mine whether a reliable conclusion can be drawn from the data to plan one or more interim analyses of the data to be considered.

Because the disadvantage of possibly enrolling more patients than are not performed because a casual observation of the data showed interesting or promising results.

Interim Analyses of Accumulating Data
During a clinical trial, data accumulate sequentially and contain increasingly more information on the effectiveness of the treatments being compared. Often, however, these data are not analyzed until the trial has been completed and all patients have been enrolled. This type of fixed sample size design has not analyzed until the trial has been completed and all patients have been enrolled. This type of fixed sample size design has increased the amount of information on the effectiveness of the therapies are most effective in clinically important subgroups of patients.

Any group of patients is heterogeneous; this is especially true for groups of patients defined by presenting signs and symptoms in an emergency department setting. Some of the patients within such a group may have a more severe form of the disease in question, and some patients may have a coexisting disease that modifies the original disease process. Almost any group of patients can be considered to have multiple subgroups, each of which is more homogeneous than the overall group.

Because of this heterogeneity, a treatment effect that is detected within the entire group may or may not exist for a particular subgroup of the original population, or vice versa. Therefore, the data from subgroups of patients are often analyzed separately. In some circumstances, this is important in determining which therapies are most effective in clinically important subgroups of patients.

When subgroups of patients are to be analyzed, they should be defined prospectively. Unfortunately, studies with an overall negative result may emphasize a positive treatment effect found only in a subgroup defined after data collection. Although such findings may warrant brief discussion and further investigation, they are unreliable because analyzing data from all possible after-the-fact subgroups requires the use of multiple statistical comparisons, which increases the chance that the finding represents a type I error.

Even if the subgroups were defined before the acquisition of any of the clinical trial data, testing for a treatment effect in each subgroup potentially increases the risk of a type I error. Also, because each subgroup of patients is smaller than the entire study population, the analysis of these subgroups may have low statistical power, which increases the chance of a type II error.

Additional problems can occur if the subgroups of patients are not defined properly. A “proper” subgroup of patients is defined by signs, symptoms, or laboratory results that are available at the initial presentation and that are not modified by the treatments being compared. An “improper” subgroup of patients is defined by signs, symptoms, or laboratory findings that can, in principle, be modified by the treatments being administered. For example, in a study that compares different volumes of fluid resuscitation for patients with septic shock, an improper subgroup of patients might be defined by a low systolic blood pressure after fluid administration (the so-called refractory shock group). Conversely, a proper subgroup would be defined by a low systolic blood pressure before any fluid administration.

Because of the possible association between the subgroup assignment and the treatment being administered in an improperly defined subgroup, improper subgroups cannot be used to assess the effectiveness of therapies. It is a common error in many retrospective studies to compare such improper subgroups of patients. When reading a study reporting results in subgroups of patients, one should look to see that the subgroups were prospectively and properly defined and consider whether the characteristics defining the subgroup are available in the emergency department.

Multivariate Models
Multivariate modeling is a statistical tool used to determine the association between two or more independent (predictor) variables and a single dependent (outcome) variable. For example, a multivariate model might be used to determine the simultaneous effects of the patient’s age and initial systolic blood pressure on the patient’s chance of survival after penetrating abdominal trauma.
The two most common types of multivariate models in medical literature are multivariate linear regression models and multivariate logistic regression models. Linear regression models are used to determine the effects of two or more variables on a continuous outcome variable, such as blood pressure. Logistic regression models are generally used when the outcome is binary, such as survival (lived vs. died) or admission to the hospital (admitted vs. discharged).

Multivariate models offer several advantages over univariate analyses. In a univariate analysis, the effect of a single predictor on the outcome is studied in isolation, often using the statistical tests discussed previously. Multivariate models are more akin to “real-life” clinical decision making, whereby a clinician considers several factors such as demographics (e.g., age and gender), history elements, and physical examination findings in deciding a patient’s likely diagnosis or clinical course. They can determine which subsets of variables have significant effects on the outcome.

Multivariate models allow one to control for confounders, variables associated with the predictor one wishes to study that may also affect the outcome. For example, in studying the effect of alcohol intake on the outcome of lung cancer diagnosis, tobacco smoking may confound the findings because patients with high alcohol intake are more likely to also smoke, and smoking increases lung cancer. A multivariate model that includes both predictors, alcohol intake and smoking, allows one to look at the isolated effect of alcohol intake while holding the effects of other predictors (smoking) constant.

An example of this phenomenon was illustrated in a study of the predictors of mortality in patients with ruptured abdominal aortic aneurysm. Univariate analysis did not reveal the emergency department-to-operating room time interval to be a significant predictor of mortality, whereas in the multivariate model, prolonged emergency department-to-operating room time was clearly a significant predictor. Patients with longer emergency department-to-operating room times likely presented with other findings that made their diagnosis less clear, or the need for intervention appear less urgent, and that were also associated with improved survival, such as higher initial systolic blood pressure and higher hematocrit. In the multivariate model, the effect of emergency department-to-operating room time could be assessed while holding such confounders as initial blood pressure and hematocrit constant.

The disadvantage of multivariate modeling is that it is more complex than univariate analysis. Certain statistical assumptions must be met, such as normal distribution of the outcome and independence of the predictor variables. Sometimes a single data point with an extreme value for a predictor or outcome variable, termed an outlier, exerts undue effects in the model. Regression diagnostics should be performed to assess the statistical assumptions have been met and that no outliers are exerting undue effect.

If two or more predictor variables interact (e.g., alcohol intake exerts an effect only in men, and not women, such that there is an interaction between the two predictors alcohol intake and gender), an interaction term must be included in the model. If two or more predictor variables give redundant information (e.g., the predictors age and arrest etiology may give redundant information for the outcome survival from pediatric cardiopulmonary arrest because the vast majority of infants have an arrest etiology of sudden infant death syndrome), the model is said to have multicollinearity, and this may require revision of the model.

Authors should report statistics that measure the “goodness of fit,” or how well the model explains the observed data. However, the model may display good fit using these statistics and still be missing an important predictor variable or contain more predictor variables than necessary. Ultimately, investigators and readers need to have a basic understanding of the disease under study to determine that all the likely significant predictors have been accounted for in the model.

When reading studies using multivariate models, one should look for the use of independent predictor variables that make clinical sense. One should check the reporting of statistics measuring goodness of fit as well as discussion of regression diagnostics performed.

Importance of Prior Probabilities

Occasionally, statistical tests yield surprising results. Unexpected results are especially difficult to interpret using classic hypothesis testing. Consider a clinical trial that uses a randomized, double-blind controlled design to compare two antibiotics for prophylaxis of infectious complications of tube thoracostomy, with the development of local wound infections or empyema as the primary endpoint. Suppose no statistically significant difference is found in the rate of infectious complications, but a statistically significant difference in mortality is noted between the two treatment groups (P = .03). It seems inherently unlikely that the choice of prophylactic antibiotic would affect survival without affecting the infection rate. This is an example in which the apparent conclusion of the trial has a very low a priori probability of being true. In other words, the a priori probability that the choice of prophylactic antibiotic could influence survival after traumatic injuries without affecting infection rates is exceedingly small.

Two possible explanations exist for such results. First, the antibiotic may have a true effect on survival by a previously unknown mechanism. The results of the trial would then be a true positive. Second, the results of the study might be a type I error, with the statistically significant P value occurring by chance, even though the antibiotic has no effect on survival. The second explanation seems more likely than the first because the chance that the antibiotic exerted its effect through a previously unsuspected mechanism is small. Thus, despite the fact that a statistically significant P value was obtained, it is unlikely that a true treatment effect exists. Classical hypothesis testing is most likely to be misleading when the alternative hypothesis being tested has a very low a priori probability of being true.

The chance of any particular interpretation of data being correct depends both on the a priori probability of that conclusion being true and on the data supporting that conclusion. An entire branch of statistical reasoning, Bayesian statistics, has been developed to incorporate a priori information quantitatively into the interpretation of data. Bayesian analysis is analogous to usual clinical reasoning in which laboratory test results are interpreted in light of the patient’s underlying risk of disease. For example, the proper interpretation of non-specific T wave abnormalities in an electrocardiogram (ECG) depends on the patient from whom the ECG is obtained. If the ECG is obtained from a patient with multiple cardiac risk factors and typical ischemic chest pain, the T wave abnormalities should be considered suggestive of myocardial ischemia. If, on the other hand, the ECG is obtained from a young, healthy adolescent with a very low chance of having cardiac disease, the T wave abnormalities should be considered a normal variant. This use of a priori risk of disease in interpreting data is common in clinical practice. Similar logic should be used in the interpretation of data from a clinical study, especially when the conclusion would have been considered very unlikely before the study was performed.

When reviewing studies, one should consider the results in the context of one's knowledge base. Is there scientific basis...
for the results? Are the results in congruence with other research in this area? Have the results been corroborated in subsequent studies?

Data Dredging or Torturing

It is surprisingly common for large databases containing many hundreds or even thousands of patient records to be created without clear prior definition of what questions are to be asked of the data. A typical example of this type of database is a trauma registry. When such databases are analyzed, the number of different questions that could be asked (or hypotheses tested) is enormous. In the case of a trauma registry, many tens of variables potentially associated with an adverse outcome are collected. It is tempting to test statistically for an association of each of these variables with survival in an attempt to find combinations of variables that predict outcome. When such exploratory data analyses are performed without clearly defined hypotheses, the analyses may entail a very large number of statistical tests. Each one of these statistical tests carries the risk of a type I error. If enough hypotheses are tested, one is virtually assured of obtaining some statistically significant $P$ values, even if none of the variables are associated with outcome.

Multiple comparisons are also made, although only implicitly, when large collections of data are visually inspected by an investigator searching for trends or associations. The investigator may make dozens of mental comparisons, most of which show little obvious difference among the groups being compared. Often, however, some “interesting” differences are noted and brought to the attention of the statistician for statistical testing. The statistician may then find a statistically significant difference but is unaware that many comparisons were made by the investigator in searching for one or a few promising comparisons.

This process of making a large number of implicit or explicit comparisons in searching for possibly important differences is called data dredging or, more pejoratively, data torturing.

Such undirected analyses of large databases virtually always yield statistically significant $P$ values that are meaningless. Thus, even when working with large collections of data, it is essential that the comparisons to be made are defined before the inspection or collection of the data and that the total number of comparisons is kept to a minimum. The risk of false-positive results from data dredging is especially high when the hypotheses tested were unlikely to have been chosen before the data collection. In other words, hypotheses that are motivated by the same data used to test them are much less likely to be true than hypotheses that are defined before the data collection, based on independently known associations or concepts.

Not all studies performed on large preexisting databases are examples of data dredging. When reviewing such studies, one should look to see that the hypothesis was defined prior to any manipulation of the database. The hypothesis should be based on independent observations and corroborated by previous research (basic science, animal, or clinical).

Intention-to-Treat Analysis

The effectiveness of any therapy is determined both by the therapy’s inherent efficacy and by the emergency physician’s ability to administer the therapy to the patient. For example, in the case of an oral medication, the effectiveness will be decreased if patients find the medication’s side effects to be intolerable and are noncompliant. Similarly, an invasive procedure will be less effective, on average, if it can only be performed successfully in a minority of patients. To estimate accurately the effectiveness a therapy will have in clinical practice, the emergency physician must properly account for those patients for whom a treatment is initiated but cannot be completed. This is the purpose of an intention-to-treat analysis.

In an intention-to-treat analysis, patients are considered to be members of the treatment group to which they were originally assigned, regardless of whether they take the prescribed medication or the appropriate therapy is successfully administered to them. For example, in a trial that examines the use of an oral agent, patients would be considered to be part of the test group if they were originally prescribed the test medication, even if they freely admit to never having taken any of the tablets.

In a study of out-of-hospital intubation, children were randomized to receive bag-valve-mask (BVM) ventilation alone or BVM ventilation followed by endotracheal intubation (Fig. 195-2). The populations of children were inherently heterogeneous; some children had sudden infant death syndrome, and others had closed head injury. The initial population was well randomized to the two interventions. Children with sudden infant death syndrome were substantially easier to intubate (because of their flaccid state) in the out-of-hospital setting than children with closed head injury, but their overall survival rate was much lower.

The goal of the analysis of the data was to determine the effect of out-of-hospital endotracheal intubation on survival. The correct way to group the data is to consider all patients initially assigned to the endotracheal intubation group as belonging to that group, whether or not they were successfully intubated. Thus, of 199 patients, 116 patients were assigned to the endotracheal intubation group and 83 patients were assigned to the BVM ventilation group. Considering all patients in the endotracheal intubation group, whether or not they were successfully intubated, the overall survival rate is 7.7% (9/116). Similarly, considering all patients in the BVM ventilation group, the overall survival rate is 9.6% (8/83). Thus, the results of the study show a small trend toward improved survival with BVM ventilation.

Alternatively (but incorrectly), one might group the data according to the treatment actually received. In this case,
children initially assigned to the endotracheal intubation group but not successfully intubated might be considered to be members of the BVM ventilation group because that was the treatment they actually received. If one counts all children who received only BVM ventilation, the overall survival rate in that group is 10.8% (16/148). Similarly, if one considers only children who were successfully intubated as the members of the endotracheal intubation group, the overall survival rate in that group is only 2.0% (1/51). This is because more children with sudden infant death syndrome are successfully intubated because of their flaccid state, but these children have lower survival rates. Similarly, children with closed head injury may be more combative and difficult to intubate but have higher survival rates than those with sudden infant death syndrome. This type of analysis then suggests that endotracheal intubation is extremely harmful. Whenever there is an association between compliance or the ability to administer an intended treatment and the patient’s baseline chance of a successful outcome, analysis by treatment received does not accurately estimate the effect of the therapy in an actual patient population.

Even when an intention-to-treat analysis is used to analyze study results, extrapolation of the results to the general population may be unreliable if the compliance in the general population is lower than that in the study population.68 This is a common problem because study populations tend to be highly compliant compared with the general population. When reviewing a study, one should look for an intention-to-treat analysis rather than analysis by treatment received. In addition, one should assess whether one’s patient population is likely to be as compliant as the study population or, in the case of a procedure, whether one is likely to be able to perform the procedure with the same rate of success.

Meta-analysis

Meta-analysis, or systematic review, is a statistical method for quantitatively combining the results of multiple clinical trials that investigate identical or similar therapies for a specific disease to obtain more accurate estimates of the effectiveness of the treatment.69 Unlike the traditional review article, a meta-analysis emphasizes the quantitative estimation of the treatment effect observed in all the available studies taken as a whole and usually provides an estimate of the reliability or quality of the results of each study. Meta-analyses can be powerful tools in practicing evidence-based medicine because they collate the results of many or all available studies.70

Studies with poor design have been shown to be more likely to find an apparent positive treatment effect. A meta-analysis that includes many poorly designed studies tends to bias the results toward showing a positive treatment effect, even if no such effect exists. Methods for controlling and measuring the effect of poorly designed studies on the results of the meta-analysis have been developed and are often termed sensitivity analyses.71 One method is to first perform the meta-analysis using only studies of the highest quality and then to sequentially include studies of increasingly lower quality to determine whether this causes a directional shift in the results. This approach requires a relatively objective measurement of study quality. Numerous scales and methods for defining study quality have been developed.72,73

Publication bias, whereby smaller studies with negative results (i.e., no treatment effect shown) are not submitted for publication, may affect the validity of the conclusions drawn by a meta-analysis.74 Authors of meta-analyses must strive to include all available trials, often requiring search strategies beyond a simple MEDLINE search. Other methods may include hand searching of relevant review articles and identified studies’ reference lists, contacting commercial sponsors and investigators to seek unpublished data, and searching nontraditional bibliographical databases.74 Problems can arise when pharmaceutical companies withhold data from commercially sponsored trials.72

Funnel plots are used to assess for publication bias.71 Authors plot trial size or quality score against treatment effect. One would expect a funnel-shaped plot, whereby smaller and lower quality trials have a wide base centered around the mean treatment effect, whereas larger and higher quality studies, because they provide more accurate estimates of the treatment effect, make up the narrower top of the funnel. If a portion of the funnel is missing, such as the smaller studies with no treatment effect, this is indicative of publication bias.

Sometimes discrepancies arise between meta-analytic results and subsequent results from a large randomized clinical trial, leaving the reader wondering which results are correct.75 Discrepancies may be due to bias introduced in the meta-analysis due to heterogeneity of studies included, poor quality of studies included, or publication bias.75,76 Discrepancies may also be due to differences in inclusion or exclusion criteria or in definitions of outcomes. For example, a meta-analysis of studies that included patients at high risk for pre eclampsia found calcium supplementation to be effective prophylactic therapy, whereas a single large trial that included only low-risk patients found calcium supplementation to have no effect.77 Because of the inclusion of multiple trials, a meta-analysis may incorporate results from thousands of patients, and small treatment effects may reach statistical significance. Such small treatment effects may be false positives arising from inadvertent bias in poorly designed studies or from an artifact of the meta-analysis. Alternatively, the results may be true but clinically unimportant, or they may be true, clinically important, and warrant a change in clinical practice. The discerning reader must consider the size of the treatment effect and possible bias introduced by the meta-analysis methodology and studies included to determine which of the previous conclusions is most likely.

When reviewing a meta-analysis, look for (1) assessment of the quality of trials included, (2) comprehensiveness of the search strategy for studies to include and assessment of possible publication bias, (3) narrow confidence intervals indicating a large number of patients, and (4) the majority of the highest quality studies to agree with the overall conclusion. Even when results are statistically significant, consider whether the size of the treatment effect is clinically significant and, combined with consideration of the costs and risks of the therapy, warrants a change in clinical practice.

Changing Practice Based on a Research Study

After reading the publication of results from a clinical research study, clinicians must decide whether the results of the study should cause them to change their clinical practice. There are several factors to consider when making this decision, the most obvious being the quality of the study and the results themselves. Other factors to consider include the context of the study within the available literature; the similarity of the clinician’s practice setting and the clinician’s likely ability to achieve results similar to those in the study; and the risks, benefits, and costs of changing clinical practice.78

For the clinician to change clinical practice based on the results of a study, first the study must be high quality. Generally, well-done systematic reviews of multiple randomized clinical trials provide better evidence than a single randomized
Guidelines and editorials may help the clinician weigh the evidence. If the current study is an outlier in its conclusions, and equally high-quality studies in the literature do not support changing clinical practice, the clinician should consider waiting for further evidence. Expert guidelines and editorials may help the clinician weigh the available evidence and consider possible causes of differing results between studies.

The clinician must decide whether the study’s patient population and health care practice setting is similar enough to the clinician’s to make the study results relevant to the clinician’s practice (a type of external validity). A study performed in a population from the East Coast demonstrating Lyme disease to be a common cause of meningitis may not be relevant to a clinician practicing in an area with low prevalence of Lyme disease. A study showing the utility of a particular intervention applied within 60 minutes of the patient’s arrival to the emergency department may not be relevant to a clinician who works in a health care setting that is unable to provide that intervention in the same time frame. The study’s inclusion and exclusion criteria must be closely examined to determine whether the clinician’s patient population sufficiently matches the study population, and the study protocol must be examined to determine whether the clinician would be able to

provide similar care. Often, simply by virtue of being a research study protocol with the added advantages of having research personnel focused on patient enrollment and study completion, compliance and follow-up are better than in a typical clinical setting.

Finally, the clinician must perform an informal cost analysis before changing clinical practice. If an intervention is extremely costly, even if it was shown unequivocally to provide some benefit, the costs may outweigh the benefits. Some costs may not be financial, such as potential adverse effects and “opportunity costs,” whereby receipt of one therapy results in the loss of the opportunity to receive another proven therapy. Clinical practice should only be changed when, on balance, the potential benefits outweigh the costs. This cost-benefit analysis may differ according to patient population, health-care system, and individual circumstances.

## EVIDENCE-BASED MEDICINE

Evidence-based medicine (EBM) refers to the systematic gathering of information from the medical literature, often regarding the effectiveness of a particular treatment or the diagnostic accuracy of a particular test, with the intent to apply that evidence in diagnostic or management decisions related to an individual patient.\(^{79,80}\) Although a specialized vocabulary has evolved, including both old and new terms (Table 195-6), the practice of EBM essentially involves the systematic application of long-established principles of medical literature analysis that until recently were often unknown by or impractical for the medical practitioner.

### Terms Used in Evidence-Based Medicine

<table>
<thead>
<tr>
<th>TERM</th>
<th>DEFINITION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bias</td>
<td>Tendency to yield a result that lies to one side or the other of the true value; an error that is not centered around zero</td>
</tr>
<tr>
<td>Critically appraised topic (CAT)</td>
<td>Summary of the results of an analysis of the evidence relevant to a particular clinical question</td>
</tr>
<tr>
<td>Likelihood ratio, negative (LR−)</td>
<td>Probability that a negative test result would occur in a patient with the disease in question divided by the probability that a negative test result would occur in a patient without the disease in question (generally &lt;1)</td>
</tr>
<tr>
<td>Likelihood ratio, positive (LR+)</td>
<td>Probability that a positive test result would occur in a patient with the disease in question divided by the probability that a positive test result would occur in a patient without the disease in question (generally &gt;1)</td>
</tr>
<tr>
<td>Negative predictive value</td>
<td>Fraction of patients with a negative test result who, in fact, do not have the disease in question</td>
</tr>
<tr>
<td>Number needed to treat (NNT)</td>
<td>Number of patients who must be treated with the better of two treatments so that one additional “good” outcome is obtained</td>
</tr>
<tr>
<td>Odds</td>
<td>Probability of an outcome divided by the probability of the outcome not occurring</td>
</tr>
<tr>
<td>Odds ratio</td>
<td>Odds of the outcome of interest occurring in one group of patients divided by the odds of the outcome of interest occurring in another group</td>
</tr>
<tr>
<td>Positive predictive value</td>
<td>Fraction of patients with a positive test result who, in fact, do have the disease in question</td>
</tr>
<tr>
<td>Post-test odds</td>
<td>Odds of the outcome of interest (e.g., particular disease being present), once a particular test result (positive or negative) is known to have occurred; equal to the pretest odds times the likelihood ratio for the test result obtained</td>
</tr>
<tr>
<td>Post-test probability</td>
<td>Probability of the outcome of interest once a particular test result is known to have occurred</td>
</tr>
<tr>
<td>Pretest odds</td>
<td>Odds of the outcome of interest before the test result is known</td>
</tr>
<tr>
<td>Pretest probability</td>
<td>Probability of the outcome of interest before the test result is known</td>
</tr>
<tr>
<td>Relative risk</td>
<td>Probability of an outcome in one group divided by the probability of the same outcome in another group</td>
</tr>
<tr>
<td>Reliability</td>
<td>Degree with which a clinical trial or diagnostic test is likely to yield consistent results when repeated</td>
</tr>
<tr>
<td>Sensitivity</td>
<td>Fraction of patients with the disease in question who have a positive test result</td>
</tr>
<tr>
<td>Specificity</td>
<td>Fraction of patients without the disease in question who have a negative test result</td>
</tr>
<tr>
<td>Validity, external</td>
<td>Degree to which the results from a study accurately reflect what would happen to similar patients who were not enrolled, including patients at other locations</td>
</tr>
<tr>
<td>Validity, internal</td>
<td>Degree to which a study accurately measures the outcomes for the enrolled study population</td>
</tr>
</tbody>
</table>

The fundamental steps in EBM are (1) to define the clinical question being asked in terms that can be addressed by clinical studies; (2) to gather the available medical literature related to the question defined; (3) to assess the relevance, validity, and quality of the evidence contained in each study; and (4) to summarize the available evidence so that diagnostic and management decisions can be made for the individual patient based on the recovered information.\(^{79}\)

### Step 1: Definition of Clinical Question

The first step in the practice of EBM is to define the clinical question clearly. The process of developing a well-formulated clinical question consists of several parts. First, the practitioner must define the population of patients similar to the individual patient motivating the search. The goal is to define a group of patients broad enough that they are likely to have been studied in clinical trials but specific enough that they are similar to the patient. Second, the practitioner must define the outcome of interest. The outcome of interest should be important to the patient and definable in terms of measurable quantities.

The steps required to define the clinical question in EBM practice are similar to the steps required to define a good hypothesis for a clinical trial: (1) the population for a clinical trial should be clearly defined, (2) the interventions to be used should be reasonable and well-defined, and (3) a
single clinically relevant and measurable outcome must be defined.

Step 2: Collection of Evidence

The second step in the practice of EBM is to gather the available evidence. Although a variety of resources might be used to accomplish this, the practitioner generally begins by searching one of the available electronic databases of published medical literature (e.g., MEDLINE). In addition, the physician may want to search one of the databases of known clinical trials (e.g., Cochrane Collaborative) because these databases often include the results from studies that have not been published or are not available on MEDLINE. Initially, the goal is to cast a very wide net to gather as many of the available studies as possible.

Step 3: Analysis of Studies for Validity, Reliability, and Relevance

The third step in the practice of EBM is to analyze each of the gathered studies to determine its validity, reliability, and relevance. The validity of a study is the degree to which the results are likely to represent “truth.” When the clinical question involves the effect of a therapeutic intervention, a double-blind, randomized clinical trial is generally believed to be the most valid type of study. The external validity of a study may be reduced if the patient population in the study is too dissimilar to the patient motivating the current activity or if the clinical setting is substantially different from the physician’s practice setting. Threats to internal validity include inadequate blinding, inadequate or no randomization, and use of historical controls or, worse, absence of controls.

The reliability of a study refers to the degree to which the results of the study are likely to be the same if the study were repeated in the same clinical setting using another group of similar patients. A study may have reduced reliability if the sample size is too small or if some of the study procedures were poorly defined and therefore difficult to repeat consistently (e.g., if some interventions were decided by individual treating physicians).

The relevance of a study is the degree to which the results, specifically the outcome or outcomes measured, directly address the clinical question being posed. Thus, a study is less relevant if the outcome used in the study is different than the outcome deemed most clinically important. For example, long-term survival may be the most clinically important endpoint for a particular condition, whereas the available clinical trials may use survival at 24 hours as their endpoint. This leaves open to question whether differences observed in survival at 24 hours would lead to differences in long-term survival.

Step 4: Summary of Most Useful Evidence

Based on these considerations, the practitioner of EBM proceeds to the fourth step, summarizing the available evidence from the studies that are the most valid, reliable, and relevant. For each of these studies, the size of the treatment effect or the accuracy of the diagnostic strategies should be noted. In the case of a binary outcome (e.g., lived vs. died or admitted vs. discharged), the number needed to treat is a useful measure of the size of the treatment effect. The utility of diagnostic tests is best measured by positive and negative likelihood ratios. Other useful measures of diagnostic accuracy include sensitivity, specificity, positive predictive value, and negative predictive value.

Step 5: Application to Patient and Critical Appraisal

Once the available evidence from high-quality studies is summarized, the practitioner is ready to apply the information to the care of the individual patient. To save the information, however, it is useful to create a summary of the entire EBM process, briefly describing each step and the results from each step. Such summaries are sometimes called critically appraised topics, which can be saved for future reference. Such “shortcut reviews” performed by others are available in journals or online (http://ebem.org/cgi-bin/index.php), but results must be interpreted in light of the specific study question, comprehensiveness of the search for evidence, and the appraisal process used.

SUMMARY

For the educated reader, the medical literature provides an ever-expanding view of knowledge regarding the effectiveness of medical therapy. A qualitative understanding of the concepts described in this chapter allows the emergency physician to distinguish high-quality studies with results that warrant a change in clinical practice from poor-quality studies that, at best, only suggest important questions to be studied.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
**PRINCIPLES OF OBSERVATION MEDICINE**

Observation services are an extension of emergency department (ED) services specifically designed to address unmet patient needs. Observation services improve patient care by continuing the evaluation and management of selected ED patients who would otherwise require admission for acute care services. With observation, 80% of these patients can be sent home without the need for hospitalization. The cost to evaluate and treat these patients is half that incurred by admission. In addition, the physician threshold for extended evaluation (traditionally provided with hospitalization) is lowered. Patients with atypical signs and symptoms are more fully evaluated to rule out serious conditions such as acute myocardial infarction or acute appendicitis. Thus, in addition to lower costs, there is also a simultaneous decrease in the inadvertent release home of patients with serious disease.

An ED observation unit is a designated area to provide these short-term services for up to 24 hours. Names given to observation units vary and include chest pain unit, clinical decision unit, and rapid diagnostic treatment unit. An ED-based observation unit is not a holding unit. A holding unit stems from hospital overcrowding and is an area where patients admitted to the hospital are held passively until they can be transferred to an inpatient hospital bed.

Two categories of patients benefit from extension of the usual 2- or 3-hour ED visit to up to 24 hours. One group is selected ED patients with a critical diagnostic syndrome (Box 196-1). These are patients whose diagnoses are unclear after the initial ED evaluation and who will benefit from further evaluation during observation. They are either admitted if found to have a serious disease or released home. The second group is ED patients with selected emergency conditions (see Box 196-1). Those patients not successfully treated during the traditional ED treatment period benefit from further treatment in an observation unit.

**THE OBSERVATION APPROACH**

The traditional ED encounter lasts 2 or 3 hours. The physician performs a history and physical examination and orders laboratory and radiologic tests. When the test results return, the physician either admits the patient to the hospital or discharges the patient home.

The observation approach adds a third option at the completion of the ED evaluation. The patient is treated and further tested for up to 24 hours. After the observation period, patients are then admitted to the hospital or discharged home.

Observation begins with the physician writing the observation orders. The patient is transferred to the observation unit from the main ED. An observation unit chart is started with treatment and investigations are begun. The observation orders include the clinical impression, the reason for observation, the therapeutic evaluation plan, expected outcome, criteria and time frame for disposition, and the physician responsible for the patient’s care and disposition. The responsible physician may be the emergency physician or the patient’s private physician or a consultant.

Adequate staffing of the observation unit is crucial for the success of the program. The patient receives services for an average 12 to 24 hours beyond the ED visit. The amount of nursing staff required is proportional to the type and intensity of treatments offered, the number of beds, whether the beds are monitored or nonmonitored, and the patient acuity. The average staff is one registered nurse per four to six patients in monitored beds and one registered nurse per six to nine patients in nonmonitored beds. The number of full-time equivalents of nursing staff is calculated to meet these staffing needs.

Staff nursing skills should be broad based and include the ability to care for patients of all ages with a wide spectrum of conditions. They should have the ability to provide critical care when needed and frequent assessments of patients under their care. Nurses should be able to provide prolonged patient and family interactions, including hygiene care, meals, and emotional support. These are all skills present in emergency nurses. When nonemergency nurses are recruited for the observation unit, they should be cross-trained, serving some shifts each month in the ED.

Additional physician staffing is also required for the observation unit. Managing ED patients in the observation unit for an additional 12 to 14 hours requires approximately a doubling of the physician service for a single patient. Calculations of the physician staffing for the amount of additional services will be approximately one full-time equivalent for every 2000 patients observed per year. As with the nurses, physicians in the observation unit must have broad-based knowledge and experience in the management of a wide variety of disease processes.
Emergency physicians possess the skill sets necessary for observation medicine. The emergency physician is ultimately responsible for the care of the patient and needs to provide clear leadership at all times.

Patients and staff involved in the observation process should be well informed about the goals and benefits provided by the extended service. Well-written, condition-specific, observation protocols ensure a continuum of care, including the transfer of patient care at shift change. The services provided in an ED observation unit are equivalent to inpatient services, albeit at an accelerated pace.

Consultants must be available to the observation unit as they would to any inpatient service. They provide therapeutic and management advice and assist in the serial examinations of patients as requested. The observation unit must identify needs, notify the consultant, assemble all the needed information, and carry out the consultant’s recommendations within the shortest timeframe possible.

Residents and medical students are included in the functioning of the observation unit because exposure to the observation approach is an integral part of their training program. Emergency residents specifically need training in this area of emergency medicine through clinical practice, lectures, and review of published literature. Residents from other specialties benefit from the exposure by having a better understanding of the role of observation medicine and its applicability in a select group of ED patients.

The amount and type of ancillary personnel needed in the observation unit depend on the size and type of services offered in the unit. An observation unit that offers chest pain evaluation may require different ancillary personnel than one that does not. Personnel may be from outside the department or function full-time in the observation unit (e.g., respiratory therapists). They may also be personnel who have not traditionally been available to the ED, such as psychiatric nurses. Also crucial for proper functioning of the unit are adequate secretarial and clerical staff.

The structure of the observation unit will determine its clinical effectiveness and financial viability. Models for the structure of the observation unit are reviewed in the American College of Emergency Physicians textbook *Emergency Department Design.* An observation unit that is properly designed and located adjacent to the ED will result in a 50% lowered cost compared with traditional hospital admission while providing equivalent or improved quality of patient care.

Designating and empowering an emergency physician to manage the observation unit is critical for success. The complexity of patient care is multiplied when an ED adds observation services. The manager develops and implements clinical protocols for efficient quality patient care. The manager schedules and supervises the observation unit staff and leads the continuous quality improvement team monitoring the observation unit’s functioning.

### CLINICAL CONDITIONS

#### Evaluation of Critical Diagnostic Syndromes

**Abdominal Pain**

**Traditional Approach.** Abdominal pain is one of the most frequent complaints seen in the ED and accounts for 4 to 8% of all visits. The typical ED evaluation of the abdominal pain patient includes a thorough history, physical examination, and the appropriate diagnostic tests. Within the short time frame of 2 or 3 hours, patients are given a provisional diagnosis and are either hospitalized or sent home.

**Problem with Traditional Approach.** The ED evaluation is inadequate for many patients, and in 40% of patients the origin of abdominal pain is never determined. Acute appendicitis is the most common abdominal surgical emergency and illustrates the inadequacies of the traditional approach. The diagnosis of acute appendicitis is missed in 20 to 30% of cases (false-negative decisions). In addition, 20 to 30% of patients taken to surgery for acute appendicitis are found to have no abnormality (false-positive decisions).

**Observational Approach.** With observation, the ED evaluation is extended from 2 or 3 hours to up to 23 hours (Box 196-2). After the initial history and physical examination of the patient, the physician makes an estimate of the probability that the patient actually has appendicitis. Those patients deemed to have an intermediate probability of disease are ideal candidates for the observational approach. Patients who are immunocompromised or pregnant and those at the extremes of age often benefit from observation. Elders in particular benefit from observation because surgical problems are often missed due to diminished diagnostic precision with increasing age.

During the period of observation, the patient is usually kept fasted and hydrated intravenously. Serial abdominal examinations are repeated at 4-hour intervals and laboratory tests repeated as appropriate. Imaging and consultations are also arranged during this time frame. Patients without appendicitis will experience improvement of their pain and have had completion of diagnostic workup and exclusion of surgical disease. Patients should be hospitalized if they have no improvement, have clinical deterioration, or have surgical pathology diagnosed by testing. In patients who do have appendicitis, signs and symptoms will continue or worsen.

**BOX 196-2** **OBSERVATION CRITERIA FOR ABDOMINAL PAIN**

- Vital signs stable
- Intermediate probability of appendicitis or
- Low probability of appendicitis with risk factor

**Risk Factors**

- Pregnant
- Elderly (>65 yr)
- Young (<3 yr)
Physician decision-making improves with observation. With observation, physicians’ false-positive surgeries can nearly be eliminated. Intensive observation with serial physical examinations at least every 8 hours rather than once per day decreases the false-positive rate from 20 to 30% to 5%. The use of a period of observation can also help identify many patients whose diagnoses may be missed during the initial ED evaluation. The appendicitis patient whose diagnosis is missed in the ED often has few clinical signs or symptoms of appendicitis on presentation, making diagnosis difficult. Physicians delaying disposition decisions on questionable cases can avoid these false-negative decisions. Because appendicitis patients develop more signs and symptoms during short-term observation, whereas those without the disorder clear their signs and symptoms, fewer patients have an unclear clinical picture after observation. With observation, a physician’s false-negative decisions (missed appendicitis diagnosis) can be significantly reduced. Missing the diagnosis at the time of initial evaluation has been found to delay surgery up to 72 hours. Complications (perforation and abscess formation) occur with delays in making the diagnosis of appendicitis and are proportional to the missed diagnosis rate. Physicians who observe rather than discharge abdominal pain patients with low probability of appendicitis lower their missed diagnosis rate, avoiding potential perforations and abscess formation.

Chest Pain

Traditional Approach. The main focus of the ED evaluation in chest pain patients is twofold: (1) assessment of the probability that the patient has an acute myocardial infarction (AMI) or acute coronary ischemia (ACI) and (2) assessment of the risk of the patient having a life-threatening event. These two assessments help determine the appropriate setting for further testing and monitoring. The probability of AMI is traditionally assessed in the ED with a directed history, physical examination, electrocardiogram (ECG), and an initial measurement of creatine kinase-MB (CK-MB) and troponin I. Patients with clear evidence of AMI on ECG are potential candidates for immediate reperfusion therapy with either thrombolytics or emergency angioplasty. This subset is at high risk for life-threatening events and best managed in the coronary care setting with close monitoring. This approach has been shown to improve survival in patients with AMI.

Depending on the evaluating physician’s threshold, chest pain patients without definite evidence of AMI at initial evaluation are generally admitted to the hospital to confirm or exclude (“rule in” or “rule out”) ACI or AMI. Patients who are judged to have low probability of ACI after the initial evaluation are released home for outpatient follow-up.

Problem with Traditional Approach. The poor performance of initial diagnostic tests makes the evaluation of chest pain highly dependent on clinical judgment. The initial ECG is diagnostic in only 50% of AMI patients, and the initial CK-MB measurement has a sensitivity of only 35%. Reliance on physician judgment has resulted in as many as 5% of AMI patients being discharged home. AMI patients not identified at the initial evaluation and released from the ED have up to a 25% risk of poor outcome. This has led to emergency physicians erring on the side of admitting patients to the hospital in an attempt to avoid missing the diagnosis of AMI. The increased sensitivity of a more liberal admission policy results in two thirds of patients admitted for chest pain having a noncardiac cause for their symptoms. The cost of this inefficiency has been estimated to be billions of dollars. Despite this liberal admission policy, missed AMI is the leading cause for malpractice suits against emergency physicians.

Observational Approach. The emergency physician can use the observation unit to extend the evaluation of patients with chest pain (Box 196-3). When used principally for such a purpose, the observation unit has been termed a chest pain unit. The chest pain unit has been successful in increasing the sensitivity and specificity of the evaluation process. Patients with low to intermediate risk of AMI are transferred to the observation unit. Patients unsuitable for observation unit evaluation include those who have a high probability of acute myocardial ischemia as evidenced by unstable vital signs, ECG findings of acute myocardial infarction, or persistent or recurring chest pain consistent with unstable angina.

The physician identifies patients with low probability for ACI by using one or more risk stratification tools. Risk stratification based on classic risk factors alone has been shown to be a poor predictor of short-term outcome. Risk stratification based on ECG findings is more reliable. The Brush ECG criteria classify low risk as the absence of ST segment elevation or depression, T wave inversion or strain, new (or presumed new) Q waves, left bundle branch block, or paced rhythm. Another useful risk stratification tool is the Goldman protocol, which uses history, physical examination, and ECG findings to classify patients into high (>70%), moderate, or low (<7%) risk. The Agency for Health Care Policy and Research criteria use the Goldman protocol to determine the risk of ischemia (low, moderate, or high) and the likelihood of complications. Another tool is the acute cardiac ischemia time insensitive predictive instrument. This uses the ECG findings, patient age, patient gender, and the presence or absence of chest pain to assign a probability of acute ischemia.

Patients admitted to the observation unit are first evaluated to rule out a myocardial infarction. They are serially tested with cardiac markers and ECGs. CK-MB estimation at 0, 3, 6, and 9 hours after presentation has 100% sensitivity, 98% specificity, and 100% negative predictive value in the detection of AMI. Other useful serum cardiac markers are the troponins (I and T) and myoglobin. Patients who present more than 24 hours after symptom onset have negative CK-MB and myoglobin testing findings, but troponin T or I remains positive for up to 6 days. Patients are monitored with continuous ECG monitors equipped with dysrhythmia alarms and memory storage capabilities. Continuous ECG ST segment monitoring can detect dynamic ST segment changes indicative of ischemia, which, when present, indicates an increased likelihood for an adverse cardiac event.

After evaluation to exclude AMI, the patient is evaluated for possible ACI. This may be performed before release of the patient from the observation unit or at follow-up evaluation within 72 hours of discharge. The most common testing modality used is exercise stress testing. Patients who obtain their target heart rate without ECG evidence of ischemia can be released home. They have an annual mortality rate of less than 1%. The performance of exercise testing depends on the ability of the patient to exercise adequately, gender (women have higher false-positive rates), interpretability of the resting....
Deep Vein Thrombosis

**Traditional Approach.** The primary objectives for the treatment of deep vein thrombosis (DVT) are to prevent pulmonary embolism, reduce morbidity, and prevent or minimize the risk of developing postphlebitic syndrome. Patients with suspected DVT are usually hospitalized when diagnostic testing is unavailable in the ED or the diagnosis has been confirmed and further management is required. Traditionally, anticoagulation with unfractionated heparin has been administered by continuous intravenous infusion for 5 to 7 days while oral anticoagulation is instituted.28 The anticoagulant response to this treatment varies markedly among patients, and therefore the dosage must be monitored by coagulation profiles.29

**Observational Approach.** The role of the observation unit in the management of patients suspected of having DVT is for diagnostic testing as well as initiation of therapy using low-molecular-weight heparin (LMWH) and patient education. Patients often present during the night or on weekends when definitive tests for DVT (e.g., Doppler ultrasonography) are not available. The patient may have a positive D-dimer test finding, which requires a confirmatory definitive test because of its poor specificity.30 In these circumstances, the patient can be anticoagulated for the short term with one dose of LMWH (enoxaparin 1 mg/kg twice daily) until the diagnosis can be clarified. If the diagnosis is confirmed, the patient can be admitted or treated as an outpatient based on hospital protocol. Patients considered for outpatient management are instructed on how to administer the medication. They are educated about DVT as well as its complications and possible side effects of the LMWH. Appropriate follow-up evaluation is also arranged before discharge. This approach has been shown to result in patients spending 67% less time in the hospital and having greater physical activity and social functioning than their standard heparin cohorts.31 Outpatient management is not recommended if the patient has proven or suspected concomitant pulmonary embolism, significant comorbidities, extensive iliofemoral DVT, active bleeding, renal failure, or poor follow-up compliance. LMWH is administered by subcutaneous injection in doses adjusted for the patient’s weight, without laboratory monitoring.

Outpatient testing with venous compression ultrasonography has become readily available.32 It is both sensitive and specific for the diagnosis of proximal (femoropopliteal) DVT.33 When repeated compression ultrasonography was compared with impedance plethysmography, compression ultrasonography was superior in detecting DVT.32 It has been proven to be a safe method of deciding when to administer anticoagulation.30 The D-dimer assay has also been shown to be a useful adjunct to compression ultrasonography in outpatient testing.

**Upper Gastrointestinal Bleeding**

**Traditional Approach.** Most patients with upper gastrointestinal bleeding (UGIB) are admitted to the hospital after initial ED assessment and stabilization.

**Problem with Traditional Approach.** UGIB is a common and potentially life-threatening condition with an overall mortality rate of 6 to 10%.34 However, most cases of UGIB are self-limited, and 80% of patients have only one bleeding episode.35

**Observational Approach.** Not all patients with UGIB do poorly, suggesting that outpatient management is possible if patients at high risk for further bleeding can be identified. Prognostic indicators include the patient’s age, heart rate, systolic blood pressure, orthostatic changes in blood pressure or pulse, color of stool or emesis, anticoagulant use, and comorbid conditions.36 In an attempt to refine diagnostic accuracy, risk assessment, and disposition, several scoring systems have been developed. Some practitioners use hemodynamic stability, intensity of bleeding, and underlying health status as predictors of rebleeding, need for surgery, and mortality.37 Some use a period of observation with early endoscopy to identify the patient who can be discharged early. Patients found to have clean-based ulcers at endoscopy have a rebleeding rate of 0 to 2% and virtually never require urgent intervention for recurrent bleeding and can be released. Utilization of this approach has been proven to be both safe and cost-effective, including a prospective clinical trial that demonstrates that 24% of patients can avoid hospitalization with cost savings of $990 per patient.38

**Syncope**

**Traditional Approach.** Syncope is caused by a spectrum of disease entities. ED evaluation includes a thorough history, physical examination, and 12-lead ECG. Patients with evidence of possible myocardial ischemia or a cardiac cause of their syncope are usually admitted to the hospital because cardiac syncope has a high risk of death (up to one third will have a poor outcome).39 Those with concomitant heart failure have a 25% mortality rate at 30 days.40 On the other hand, patients with noncardiac syncope have a low risk of adverse events (1%) and can be managed as outpatients.39

**Problem with Traditional Approach.** Attempts to exclude a possible cardiac cause for syncope usually result in 25 to 40% of patients being hospitalized for further evaluation and management.40 The traditional ED evaluation identifies only 50% of patients with a serious cause of their syncope,41 and this has often resulted in a liberal admission policy; however, one study found that only 12% of patients had a serious cause for syncope that justified hospitalization.42

**Observational Approach.** Extending the ED with a period of observation is a strategy to reduce unnecessary hospitalizations (Box 196–4). Patients with a cardiac syncope have a poor prognosis and need to be identified. These patients often do not have chest pain as a symptom, but they may have ischemic changes on ECG, arm or shoulder pain, or prior history of exercise-induced angina. A “rule out myocardial infarction” evaluation with serial ECG and enzyme measurement may be the only way to identify these patients. Prolonged ECG monitoring can point to a specific cause in up to one fifth of patients, with half of all abnormalities detected in the first 24 hours.43 The 1-year risk of dysrhythmia or death in syncope patients correlates with four factors: an abnormal ECG, history of ventricular dysrhythmia, history of heart failure, and age older
Observation Criteria for Syncope

- Low to intermediate risk of adverse event
- Stable vital signs
- Loss of consciousness <10 min
- No focal acute neurologic signs
- Normal electrolytes and blood count
- No objective evidence of ischemia or injury by electrocardiographic or cardiac markers
- No history of congestive cardiac failure

Patients with none of these risk factors have only a 4.4% rate of adverse events at 1 year and may be appropriate for outpatient evaluation. In contrast, patients with three or four risk factors have a 58% adverse outcome rate and should be admitted to the hospital. Patients with one or two risk factors have intermediate risk and may be appropriate for outpatient evaluation with observation. Patients unsuitable for observation include those who have abnormal neurologic findings, abnormal ECG or cardiac enzymes, history of trauma before syncope, or loss of consciousness for longer than 15 minutes.

During the observation period, serial examination of patients is carried out, including vital signs, with the majority of patients safely discharged home without hospitalization. Continuous ECG monitoring, consultation, serial cardiac enzymes, and further tests such as two-dimensional echography of the heart, psychiatric assessment (associated with up to 25% of cases of syncope), and tilt table testing should be arranged when appropriate. Tilt table testing is a useful investigation in patients with recurrent syncope when heart disease is not suspected. Up to 60% of patients who have vagally mediated syncope can be detected by this modality. The period of observation can also identify patients with cardiac dysrhythmias or sinus pauses who are candidates for more extensive diagnostic evaluation in the hospital.

Transient Ischemic Attack

**Traditional Approach.** More than 300,000 people suffer a transient ischemic attack (TIA) each year. For most patients, it is a transient event that will not recur if they take an aspirin each day. However, for 1 in 10 patients, it is a warning sign that they will suffer a stroke unless they are appropriately evaluated and treated. Traditionally, the patient is assessed in the ED with history, physical examination, lab tests, ECG, and head computed tomography (CT) scan. Most patients are then hospitalized for serial clinical evaluations, a neurology consultation, carotid Doppler testing, echocardiography, and cardiac monitoring.

**Problem with Traditional Approach.** The problem with the traditional approach is that most TIA patients are admitted to the hospital. After 3 days of evaluation, few will be found to have carotid or heart disease requiring an intervention. The opportunity for improvement is to develop a more cost-effective approach.

**Observational Approach.** Observation is an alternative to hospitalization for those TIA patients with a negative ED evaluation for whom the emergency physician still has concern. An accelerated diagnostic observation protocol was compared to acute care hospitalization in a prospective randomized clinical trial. All patients had full evaluation in the observation unit or inpatient floor. Clinical outcomes were equivalent with the two approaches, but the observation unit was more efficient (length of stay, 25 hours vs. 61 hours) and had lower costs ($890 vs. $1547).

There are more than 30 million trauma-related ED visits annually. Patients with serious injuries require hospitalization for definitive therapy, whereas those with minor injuries can be discharged after treatment in the ED.

The problem with the traditional ED approach is that many patients have injury patterns or actual injuries that fall somewhere between the two scenarios just described. If these patients are released home, there is a risk that some will have poor outcomes as a result of missed injuries. On the other hand, because the majority of these patients do not have serious injuries, admitting this group to the hospital will result in a waste of scarce health care resources.

Observation units have been found to be an efficient and useful strategy in the evaluation and management of trauma victims. With observation, selected patients can be evaluated further to determine the need for admission. One study of 20,000 patients treated in an ED observation unit during a 12-month period found that 3% of patients were admitted to the observation unit, with 86% safely discharged home without the need for admission.

Blunt Abdominal Injury

**Traditional Approach.** Current ED management of blunt abdominal trauma (BAT) patients includes history taking, physical examination, blood analysis, plain radiography, ultrasonography, and CT scan. After initial stabilization and exclusion of other major injuries in the ED, most patients suffering BAT are admitted to the hospital for further evaluation and monitoring.

**Problem with Traditional Approach.** The initial evaluation is inadequate for accurate disposition of many BAT patients. One third of patients who do not have any symptoms or signs suggestive of intra-abdominal injury may actually have significant injury. Also, because none of the present modalities is 100% sensitive for investigating the presence of injury, many patients with initially negative investigations are hospitalized.

**Observational Approach.** BAT patients appropriate for observation include those who, after initial evaluation, have no clear evidence of serious injury on physical examination but remain at risk for serious injury because of the mechanism of the injury or the individual’s personal health (e.g., on anticoagulants). Evaluations during observation for up to 23 hours include repeat physical examinations, laboratory testing, imaging, and specialty consultations. Patients are hospitalized if their condition deteriorates during the observation period or if, after testing, they are found to have serious internal injury. Patients with negative findings on evaluation and the ability to tolerate feeding can be safely released home. Patients who have sustained significant BAT by mechanism of injury or have equivocal findings on abdominal examination should undergo further testing, such as CT scan, to detect occult injury. Ultrasonography (focused assessment by sonography in trauma [FAST]) is being increasingly used in the initial evaluation of the patient with BAT because it is a rapid noninvasive study with 99% specificity for detecting abdominal injury. However, it cannot be used to rule out serious intraperitoneal injury because a meta-analysis of 62 trials found the overall sensitivity of FAST to be only 79%. CT alone is not adequate to rule out serious injury, with sensitivity of only 80 to 95%. Observation alone in patients with BAT is not sufficient because up to 20% of patients with significant injury will not have abdominal tenderness or develop it even after a short period of observation. Thus, the prudent approach to
patients with significant BAT without clear evidence of intra-abdominal injury is the utilization of a diagnostic test, such as CT, together with a period of observation.

Penetrating Abdominal Injury

Traditional Approach. Most patients with penetrating abdominal injury are hospitalized for further evaluation, which may include wound exploration in the operating room and additional diagnostic testing.

Problem with Traditional Approach. Many of these hospitalizations are unnecessary because only two thirds of patients with abdominal stab wounds have a breach of the peritoneum, and two thirds of these do not sustain visceral injury.

Observational Approach. A period of observation can identify those patients who do not require surgical intervention. Patients undergo serial examinations by the physician, further diagnostic testing, and specialty consultation. Those without evidence of peritoneal perforation or visceral injury after evaluation are sent home after proper wound care.

The conservative approach to penetrating abdominal wounds was developed in the 1970s. Those without peritoneal breach can be safely sent home after wound care and a period of observation without the need for hospitalization. Those with stab wounds to the abdomen with peritoneal breach but a negative finding on diagnostic laparoscopy or imaging with CT scan or ultrasonography can be safely managed in an observation unit. Patients with significant intra-abdominal injuries identified during observation are admitted; the 70 to 90% of patients without such injuries are released home.

Gunshot wounds are often more difficult to evaluate than stab wounds. However, patients who appear to have tangential gunshot wounds can avoid surgery with observation if they are hemodynamically stable and have initial negative test findings. Penetrating wounds manifest differently in children than in adults. Initial diagnostic testing with CT and diagnostic peritoneal lavage in children detects only 50% of injuries, with only 30% of patients having localized tenderness. Observation can help avoid unnecessary surgery in patients without injury and avoid missing the diagnosis in those without clear evidence of injury.

Blunt Chest Trauma

Traditional Approach. Many patients who have a history of blunt chest trauma (BCT) in high-velocity accidents are admitted to the hospital to rule out myocardial or pulmonary contusion.

Problem with Traditional Approach. Very few patients admitted to the hospital with BCT from high-velocity accidents without initial evidence of injury are found to have serious injury during hospital evaluation.

Observational Approach. Patients with isolated BCT who are otherwise stable with normal ECG are suitable for a period of observation to exclude myocardial injury. During the period of observation, patients are monitored with continuous ECG, specifically assessing for dysrhythmias. Serial enzyme determinations, such as troponin level, are also carried out to detect evidence of myocardial injury. Those patients with sternal fractures or other evidence of higher risk of intrathoracic injury should be considered for transesophageal echocardiogram.

Those with negative evaluations during the period of observation are released home for outpatient follow-up.

Much of the period of observation in patients with BCT focuses on identifying the presence and prognosis of myocardial contusions. The overall incidence of cardiac-related complications in these patients is low (0.1%). Patients with blunt cardiac trauma who have complications usually have an abnormal ECG or abnormal CK-MB or troponin level at presentation. Conversely, a normal ECG and CK-MB and troponin levels correlate with the lack of clinically significant complications.

Penetrating Chest Injury

Traditional Approach. Patients with penetrating chest injury present with a spectrum of severity ranging from severe life-threatening injury requiring urgent operative intervention to hemodynamically stable patients with a negative initial evaluation. Most patients presenting with penetrating chest injuries are admitted to the hospital. Often, even those with a negative initial evaluation are admitted to exclude serious injury to the heart, lungs, and the major blood vessels.

Problem with Traditional Approach. The accuracy of this approach is limited because many patients with evidence of injury are admitted but have no further deterioration or need for medical therapy. On the other hand, there are those without obvious evidence of serious injury who will have a negative outcome if released after the initial evaluation.

Observational Approach. A period of observation combined with diagnostic imaging can improve clinical decision-making. Patients with evidence of a small pneumothorax or hemothorax can be monitored for deterioration. Those without evidence of serious injury but of concern to the physician can likewise be observed for complications. During the period of observation, patients are monitored for respiratory or hemodynamic compromise. Repeat chest radiographs can detect the development of hemothorax or pneumothorax. Patients who deteriorate during the period of observation require hospitalization.

The safety and efficacy of managing asymptomatic stab wound victims in the short-term observation unit have been clearly established in multiple studies. A total of 5 to 15% will require hospitalization because of development of delayed pneumothorax, subcutaneous emphysema, hematemesis, or pneumopericardium. In addition, the majority of stab wound victims with small pneumothoraces or hemothoraces will be treated solely with a chest tube without further surgical intervention. Major trauma centers can manage many of these patients as outpatients without hospitalization with use of a period of observation.

Patients with penetrating wounds to the cardiac area of the chest (between the nipples), the region of the great vessels, or the thoracoabdominal area usually require more intensive testing to exclude injury not only to the heart, major vessels, and lungs but also to the diaphragm and the abdominal organs. Echocardiography may detect pericardial fluid or tamponade in patients with penetrating injury in close proximity to the heart. Patients with small effusions may be observed in a monitored setting with serial examinations, whereas patients with large effusions should be treated surgically. Patients with a negative echocardiography can be observed in the observation unit. Even patients with small effusions may have sustained a serious injury, so the intensity of monitoring needs to be high.

Treatment of Emergency Conditions

Asthma

Traditional Approach. More than 20 million people in the United States are afflicted with asthma. Acute exacerbation of asthma
is a common ED presentation, with estimated annual admissions exceeding 450,000. Traditionally, therapy is provided in the ED for 2 to 4 hours, consistent with national guidelines. Initial assessment includes history, physical examination, oxygen saturation, and peak expiratory flow rate (PEFR) or forced expiratory volume in 1 minute. Treatment consists of beta-agonists, magnesium sulfate, and steroids, where appropriate. Patients who do not improve after 3 or 4 hours of treatment are hospitalized for further management.

Problems with Traditional Approach. With this approach, one third of patients are hospitalized. This translates into an estimated medical cost of $1.2 billion annually, another pitfall in the traditional ED treatment of asthma is that short encounter times do not allow for identification and aggressive treatment of patients with a higher tensity for relapse. This leads to repeat ED visits, additional medical costs, and diminished quality of life.

Observational Approach. An alternative to hospitalization for patients failing ED treatment is the use of an extended, short-term intensive protocol for 8 to 12 hours in an observation unit. With extended treatment, 80% of such patients can be discharged home. Inclusion criteria for observation unit management are failure of standard initial management and continued respiratory distress and good response to initial management but high risk for relapse (Box 196-5). Increased risk of relapse is indicated by a history of numerous asthma-related ED or clinic visits within the past year, using more outpatient medications (including home nebulizers), and longer duration of symptoms. Exclusion criteria include unstable vital signs, evidence of impending respiratory failure (Paco2 > 45 mm Hg, PaO2 < 55 mm Hg), or severe airway restriction (PEFR < 80 L/min after first inhaled beta-agonist treatment). Exclusion criteria also include factors that correlate with unsuccessful treatment during observation. These include a previous ED visit in the past 10 days, previous intensive care unit admission or intubation, hospitalization during the previous year, three or more ED visits in the past 6 months, use of oral steroids for more than half of the previous year, and peak flow after the third beta-agonist treatment that is less than 32% of predicted.

Therapy in the observation unit is a continuation of ED treatment with handheld nebulized beta-agonists every 2 to 4 hours and repeated steroids at 6 hours after initial therapy. Patients are managed up to 23 hours but generally are admitted to the hospital if they do not respond within 12 hours. Patients are released from the observation unit when they are not in respiratory distress, have minimal residual symptoms, and have a PEFR of 70% or greater of predicted or personal best. Before discharge, there should also be patient educational activities and assessment of inhaler techniques. Patients should be initiated into daily diary keeping as well as a log of PEFR before and after treatment. Appropriate follow-up monitoring should also be arranged.

A prospective randomized clinical trial of observation versus traditional hospitalization of ED asthma patients who did not “break” in the first 3 or 4 hours of ED treatment found no difference in relapse rates at 8 weeks, but it found significant differences in the length of stay (9 hours vs. 59 hours), patient satisfaction, and quality of life and also cost savings of $1000 per patient. Patients treated in the observation unit had higher patient satisfaction according to four parameters: received service wanted, recommendation of service to others, satisfaction with service, and overall satisfaction compared with inpatient care. Observation unit patients also reported fewer problems with care received, communication, emotional support, physical comfort, and special needs. Observation has also been shown to have utility in the management of pediatric patients with asthma. Of those who would otherwise require hospitalization, 30 to 70% can be successfully managed as outpatients with the observation unit.

Atrial Fibrillation

Traditional Approach. Atrial fibrillation is a relatively common condition that occurs in 2 or 3% of adults and is the most common sustained cardiac dysrhythmia in patients presenting to the ED. The goals in management of acute atrial fibrillation are hemodynamic stabilization, symptom relief, prevention of thromboembolism, resolution of the dysrhythmia, and exclusion of serious pathologic causes of the dysrhythmia. The majority of patients who present to the ED with new-onset atrial fibrillation or acute atrial fibrillation are hospitalized.

Problem with Traditional Approach. Recently, the necessity of admitting the majority of patients with acute atrial fibrillation has been questioned. It is recognized that new-onset atrial fibrillation for most patients is a transient dysrhythmia with no serious precipitants and a benign prognosis. One retrospective analysis of 216 patients admitted for atrial fibrillation found that one third of patients did not actually require admission to the hospital.

Observational Approach. The observational approach to new and acute atrial fibrillation has been validated in a number of clinical trials. The period of observation is usually 8 to 12 hours. During observation, patients are treated to rectify their dysrhythmia and evaluated for serious precipitants of their condition. After observation, 80 to 90% of patients can be discharged home without hospitalization.

Observation extends the ED evaluation of the patient for underlying medical conditions that may have precipitated the arrhythmia (Box 196-6). These include AMI, congestive heart failure, electrolyte abnormalities, and hyperthyroidism. AMI is excluded as a precipitant with serial cardiac enzyme testing over 6 to 9 hours. The period of observation is also used to

**BOX 196-5**

**OBSERVATION CRITERIA FOR ASTHMA**

- Failed standard emergency department management
- Stable vital signs
- Peak flow after third beta-agonist >32% predicted
- No concomitant illness (e.g., pneumonia, heart failure)
- Successful emergency department management but high risk for relapse
- Risk of relapse
  - Second visit to emergency department within 10 days
  - Previous intubation or intensive care unit admission
  - Hospitalization in past year
  - Three or more emergency department visits in 6 mo
  - Oral steroids for more than 6 mo

**BOX 196-6**

**OBSERVATION CRITERIA FOR NEW-ONSET ATRIAL FIBRILLATION**

- Normal electrolytes and blood count
- Stable vital signs
- No physical finding of heart failure
- Jugular venous distention, ankle edema, S3 gallop
- No history of heart failure
- No symptoms of myocardial ischemia
- No objective evidence of ischemia by electrocardiographic or cardiac markers
detect structural heart disease with the use of echocardiography where appropriate. Patients are excluded from observation if they exhibit hemodynamic instability, comorbid conditions, heart failure, chest pain, or significant coronary artery disease.

Observation is also used to extend the treatment period of the patient. The spontaneous conversion rate for patients with acute atrial fibrillation is 50 to 70% within the first 24 hours.82 Patients who spontaneously convert have a low rate of structural heart disease.82 Those who do not spontaneously convert in the first 8 hours can be converted chemically or electrically.83 After cardioversion, the patient needs to be observed. This is especially true for patients converted with the newer class III antidysrhythmic agents (e.g., ibutilide), which have the potential for serious side effects, such as torsades de pointes (5% of patients), sinus bradycardia, and sinus arrest.83,84 The risk of thromboembolism in patients with atrial fibrillation of less than 48 hours’ duration is less than 1%, so patients who convert can be released home without need for anticoagulation.85

### Congestive Heart Failure

#### Traditional Approach.

Congestive heart failure (CHF) is highly prevalent, affecting approximately 1% of people in their 50s and increasing progressively with age to afflict 10% of people in their 80s.86 It is an increasing problem; more than 2 million Americans have the disease and 400,000 new cases are diagnosed each year.86 One third of patients with CHF require hospitalization each year, one third get readmitted each year, and one third die within 2 years.86 The annual cost to the health care system of managing patients with heart failure admitted to the hospital has been estimated as $28 billion.87 Between 80 and 87% of patients diagnosed with CHF are hospitalized.87-88

#### Problem with Traditional Approach.

CHF is highly prevalent, affecting approximately 1% of people in their 50s and increasing progressively with age to afflict 10% of people in their 80s.86 It is an increasing problem; more than 2 million Americans have the disease and 400,000 new cases are diagnosed each year.86 One third of patients with CHF require hospitalization each year, one third get readmitted each year, and one third die within 2 years.86 The annual cost to the health care system of managing patients with heart failure admitted to the hospital has been estimated at $28 billion.87 Between 80 and 87% of patients diagnosed with CHF are hospitalized.87-88

#### Observational Approach.

Observation is a strategy to avoid hospital admission of patients with CHF that results in great cost savings (Box 196-7). Selected patients can be safely managed in an observation unit.87-89 Such patients include those with a high probability of successful treatment with short-term extension of the ED visit. Patients should also have low severity of illness. They should not be hypoxic, should not have pulmonary edema or hypotension, and should not have objective evidence of AMI, hemodynamic instability, or serious comorbid conditions.87-89 B-type natriuretic peptide (BNP) has been used to streamline decision making. Patients with BNP levels between 100 and 500 pg/mL are suitable candidates for observation unit care because a large proportion of these patients should be able to be discharged home. The test has a negative predictive value of greater than 95% and a positive predictive value of 70 to 95%. It correlates with pulmonary capillary wedge pressure, and because its half-life is less than 30 minutes, serial measurements during observation can evaluate the effects of therapeutic interventions.90,91

### Dehydration

#### Traditional Approach.

Dehydration is often the presenting symptom of an underlying disease state and can affect the very young to the very old. Patients are often admitted for intravenous hydration to correct fluid and electrolyte imbalances or for further diagnostic evaluation.

#### Problem with Traditional Approach.

Patients with dehydration are often hospitalized because short ED visits do not allow for full correction of fluid and electrolyte disorders or extensive evaluation for underlying causes. A common cause of ED return visits is dehydration due to initially inadequate therapy and evaluation.92

#### Observational Approach.

The goals of observation unit therapy are adequate treatment of fluid and electrolyte abnormalities and identification of the underlying cause of symptoms. Appropriate patients for observation include those with acceptable vital signs and mild to moderate dehydration (Box 196-8). They should have self-limited or treatable causes not requiring hospitalization, with mild to moderate electrolyte abnormalities. Another group of patients appropriate for observation are those with hyperemesis gravidarum. Patients unsuitable for observation are those with unstable vital signs, cardiovascular compromise, underlying chronic medical illness, severe dehydration or electrolyte abnormalities, or associated condi-
Infections

Pneumonia

**Traditional Approach.** Each year, approximately 600,000 patients are hospitalized with pneumonia, at a cost of almost $4 billion.95 Many of these patients are admitted after initial ED evaluation. Physicians often rely on subjective criteria such as clinical appearance when selecting patients for hospital admission.96

**Problem with Traditional Approach.** There is great variation in the admission rates for pneumonia.97 Emergency physicians tend to overestimate the risk of death in patients with pneumonia, which has resulted in many low-risk patients being hospitalized unnecessarily.96

**Observational Approach.** Observation is appropriate for those patients whom the physician is concerned may not do well as outpatients (Box 196-9). This concern can be based on physician clinical judgment or a severity of illness index. Fine and associates96 developed a prediction rule to estimate which pneumonia patients would be at higher risk for mortality. They reviewed medical records of more than 14,000 patients hospitalized with pneumonia and identified 14 key clinical variables (e.g., age, sex, coexisting illness, vital signs, and mental status) and 7 key laboratory variables (e.g., blood urea nitrogen, glucose, hematocrit, arterial oxygen, and pleural effusion on chest radiograph). They then weighed each of these variables into a cumulative point total (PSI index) and assigned each patient to one of five mortality risk groups ranging from class I, which includes patients with a low risk (60-day mortality risk <0.5%) who can be treated as outpatients, to class V, which includes patients with a high risk (60-day mortality risk >30%) who should be treated as inpatients. Patients in class III are at intermediate risk, and traditionally one half are admitted and one half are treated as outpatients. By use of the PSI to risk stratify patients, physicians can avoid hospitalization of many low-risk patients.96 Intermediate-risk patients (class III) are good candidates for a period of observation to clarify their need for hospitalization. Irrespective of the patient’s risk as judged by PSI, some patients are not appropriate for observation but should be admitted: those with immunocompromise, pulmonary tuberculosis, high suspicion of pulmonary embolism, or hypoxia (Table 196-1).

During observation, patients are treated with antibiotics, oxygen therapy, and pulse oximetry monitoring. Hydration is given either orally or intravenously. After 10 to 12 hours of treatment in the observation unit, the patient is reevaluated and a decision about disposition is made. Patients who deteriorate during the observation period or have a saturation of less than 90% on room air after observation should be admitted to the hospital.

**Pyelonephritis**

**Traditional Approach.** Pyelonephritis is a serious infection that frequently results in hospitalization for intravenous hydration and antibiotic administration.

**Problem with Traditional Approach.** Many patients who are admitted with pyelonephritis are judged retrospectively not to have had the condition. In addition, many patients with pyelonephritis are at very low risk for developing complications.

**Observational Approach.** Observation is appropriate for adult, nonpregnant women who appear to have uncomplicated pyelonephritis. Patients receive an initial dose of intravenous antibiotic, intravenous fluids, antiemetic, and antipyretic. Laboratory tests include complete blood cell count, urinalysis, and

**Box 196-9 Observation Criteria for Pneumonia**

Low risk of death (1–5%): clinical judgment or severity index

No risk factors for poor outcome: immunocompromised, neuromuscular disorder, pulmonary tuberculosis, cystic fibrosis

No objective evidence of ischemia or injury: electrocardiographic or cardiac markers
urine and blood cultures. Patients who are clinically stable and able to tolerate oral fluids are released home after 12 hours of treatment.

Outpatient management of selected pyelonephritis patients with observation has been shown to be safe and effective. Only 5 to 25% of patients require hospitalization after the period of observation.\textsuperscript{99,100} At 3-week follow-up examination, 2 to 6% have developed complications and require hospitalization.\textsuperscript{99,100} With a period of observation and careful follow-up evaluation, selected patients with pyelonephritis can be successfully managed without hospital admission.\textsuperscript{100}

\textit{The references for this chapter can be found online by accessing the accompanying Expert Consult website.}
Emergency ultrasound (US) is the simultaneous performance and interpretation of sonographic examinations at the bedside of the patient in a focused manner to diagnose, monitor, and treat emergency medical conditions.1,2

Emergency US is an emergency clinician-performed study.1,3,4 Although the operator is typically an emergency physician,1,3,4 he or she may be an emergency physician assistant, nurse practitioner, emergency medicine (EM) resident, or trained emergency nurse or paramedic—all under the supervision of a trained, credentialed emergency physician.5,6 Emergency physicians who have advanced training in ultrasound imaging are also known as emergency sonologists. Emergency US is typically performed in hospital emergency departments but may also be performed in other areas of the hospital, emergency stand-alone centers, out-of-hospital mobile transport such as ambulances or helicopters, disaster scenarios, military engagements, international rescue work, and remote settings such as space, sea, or land centers with limited or no medical access.1,7-14

Emergency US is a different paradigm in which the same physician or clinician performs and simultaneously interprets the examination in addition to integrating the results in the clinical scenario.1,15 This is unlike other specialties, such as radiology, cardiology, and obstetrics and gynecology, that often use a trained technologist to perform the examination and a physician in that specialty to interpret or “read” the examination.16,17

Emergency US examinations are typically focused examinations of an area of the body, organ system, or physiologic pattern or goal-directed investigations of an emergency symptom or sign. Not all pathology will be detected by such examinations. Additionally, the physics of ultrasound may limit the detection of pathology or create pseudopathology that causes diagnostic difficulty. The primary limitation of such studies is the experience and skill of the performing physician.

**HISTORY**

A half century of scientific work in many countries produced the initial clinical medical uses of US in the 1950s by physicians interested in its advantages over traditional imaging, including noninvasiveness, lack of ionizing radiation, and superior resolution.17

Emergency physicians started using US in the 1980s as a way to rule out emergent “silent” diagnoses, such as ectopic pregnancy, intraperitoneal hemorrhage, hemopericardium, cholelithiasis, renal colic, and aortic aneurysm. A model curriculum was created by a Society for Academic Emergency Medicine (SAEM) task force that initiated formal guidance for emergency US programs.18,19 Due to resistance within hospitals from traditional imaging specialties such as radiology and cardiology, the American Medical Association House of Delegates, led by the American College of Emergency Physicians (ACEP), carried a resolution suggesting that hospital credentialing committees follow specialty-specific guidelines for US-based credentialing.20

Specialty-specific guidelines were created in 2001 by ACEP that specified emergency US scope of practice, primary applications, training pathways, the number of procedures required for training prior to credentialing, quality assurance and documentation guidance, and training course outlines.1 Today, more than 95% of emergency medicine residencies teach US, and approximately 30% of community hospitals have instituted bedside US performed by emergency physicians.21,22 New applications are being described, including procedural guidance.

**TRAINING, CREDENTIALING, AND ACCREDITATION**

Emergency US is one of three competency assessments required of EM residents by the Residency Review Committee for Emergency Medicine.6,23,24 For emergency physicians in practice, initial training often takes place through continuing medical education courses followed by a period of proctoring or supervision.1,25

**APPLIED ULTRASOUND PHYSICS AND INSTRUMENTATION**

By definition, US is sound greater than 20,000 Hz; US is a longitudinal, mechanical, and directional wave that is transmitted through mediums. US is kinetic energy, so all users of this technology should use the ALARA (as low as reasonably achievable) principle by performing procedures only when needed and limiting the time of sonographic investigation.26

US waves are characterized by their amplitude (deflection from a baseline), wavelength (the wave cycle distance, usually measured in microns), and frequency (the number of cycles per second). Modern diagnostic US transducers emit at millions of cycles per second or MHz. The frequency of the transducer can be adjusted to improve image quality; lower
EQUIPMENT

A variety of US machines are available, including palm size, laptop, cart based, and combination devices. US machines have controls for gain, depth, and freeze and have print or acquire image controls. Additional controls including TGC, frame rate, measurement, dynamic range, M-mode, power Doppler, color directional Doppler, spectral Doppler, patient ID, transducer selection, and image review. Images are produced in digital stills, digital video clips, thermal paper stills, or DVD or video recordings.

Modern multifrequency probes can select among several US frequencies to maximize either tissue penetration or image quality depending on the application. Probe design and footprints (the actual transducer surface area touching the patient) can be divided into three categories: flat linear array probes, curved linear array probes, and phased array probes. Flat linear probes give a square or rectangular picture with excellent lateral resolution at the expense of width of field. Curved linear array probes, which give a wider field of view at the expense of lateral resolution, are usually used for deep tissue penetration applications, such as evaluation for pregnancy or abdominal aortic aneurysm. The endocavitary probe is a highly curved linear array probe that is most commonly used for endovaginal evaluation. Phased array probes offer a smaller footprint than curved linear array probes and were originally developed for cardiac evaluations, but they can also be used for abdominal studies. They offer excellent image quality for the evaluation of moving structures but with worse resolution of static structures.

APPLICATIONS AND CATEGORIZATION

In 1994, SAEM categorized US applications broadly into abdominal, cardiac, obstetric/gynecologic, and special applications. In 2001, ACEP developed specialty-specific guidelines that categorized applications more narrowly to include trauma, pregnancy, abdominal aortic aneurysm (AAA), and cardiac for pericardial effusion and cardiac activity, biliary, renal, and procedural applications. Recent studies have investigated emergency US in diagnosing deep vein thrombosis (DVT) and pneumothorax. New applications include soft tissue, ocular, and musculoskeletal studies. Therapeutic applications of transcranial Doppler are being studied by emergency physicians.

**Window**—soft tissue where transducer is placed to interrogate tissue in the body

A variety of US machines are available, including palm size, laptop, cart based, and combination devices. US machines have controls for gain, depth, and freeze and have print or acquire image controls. Additional controls including TGC, frame rate, measurement, dynamic range, M-mode, power Doppler, color directional Doppler, spectral Doppler, patient ID, transducer selection, and image review. Images are produced in digital stills, digital video clips, thermal paper stills, or DVD or video recordings.

Modern multifrequency probes can select among several US frequencies to maximize either tissue penetration or image quality depending on the application. Probe design and footprints (the actual transducer surface area touching the patient) can be divided into three categories: flat linear array probes, curved linear array probes, and phased array probes. Flat linear probes give a square or rectangular picture with excellent lateral resolution at the expense of width of field. Curved linear array probes, which give a wider field of view at the expense of lateral resolution, are usually used for deep tissue penetration applications, such as evaluation for pregnancy or abdominal aortic aneurysm. The endocavitary probe is a highly curved linear array probe that is most commonly used for endovaginal evaluation. Phased array probes offer a smaller footprint than curved linear array probes and were originally developed for cardiac evaluations, but they can also be used for abdominal studies. They offer excellent image quality for the evaluation of moving structures but with worse resolution of static structures.

**APPLICATIONS AND CATEGORIZATION**

In 1994, SAEM categorized US applications broadly into abdominal, cardiac, obstetric/gynecologic, and special applications. In 2001, ACEP developed specialty-specific guidelines that categorized applications more narrowly to include trauma, pregnancy, abdominal aortic aneurysm (AAA), and cardiac for pericardial effusion and cardiac activity, biliary, renal, and procedural applications. Recent studies have investigated emergency US in diagnosing deep vein thrombosis (DVT) and pneumothorax. New applications include soft tissue, ocular, and musculoskeletal studies. Therapeutic applications of transcranial Doppler are being studied by emergency physicians.
The most common uses of US by community emergency departments in decreasing order are trauma, cardiac (cardiac arrest and pericardial effusion), AAA, pelvic, biliary, procedural, renal, and DVT. Procedural guidance can assist many emergency percutaneous procedures such as vascular access, torso cavities evacuation (e.g., thoracentesis, paracentesis, and pericardiocentesis), arthrocentesis, lumbar puncture, abscess drainage, nerve blocks, and other percutaneous procedures.

Emergency US is used in clinical pathways or algorithms to rapidly identify or exclude emergency medical conditions.

**Trauma Ultrasound**

The trauma US exam is also called the focused assessment with sonography in trauma (FAST) examination. The trauma examination originally focused on the peritoneal space, as an evaluation for hemoperitoneum, using the right flank, left flank, and pelvic windows for detection of dependent peritoneal fluid and pleural effusion. Newer versions include the EFAST (extended FAST) for the evaluation of potential pneumothorax and FASTER for evaluation of the extremities.

The FAST exam is based on the premise that fluid within the peritoneum circulates throughout the abdomen and pelvis and settles in dependent spaces. The volume of fluid required for a positive US depends on the site of injury and site of sonographic detection but generally 250 mL or greater is required, and nearly 600 mL of fluid is necessary to cause a positive flank stripe when fluid is from the pelvis. Pericardial fluid is contained within the parietal and visceral pericardium. Once a certain volume is reached, the pressure in the pericardial space increases exponentially, causing pericardial tamponade. Generally, 50 mL is required to cause a hemodynamic compromise in a patient without prior pericardial inflammation. However, tears in the pericardium that communicate with the pleural space or even the peritoneum can cause false-negative exams. Pleural fluid can be detected by US, but this is dependent on the position of the body. Pneumothorax detection is based on the absence of the normal sonographic sliding of the visceral and parietal pleura.

The indications for the torso trauma US examination (often called the EFAST) include the need to detect any of the following in an injured or ill patient: pathologic free intraperitoneal fluid (typically hemoperitoneum, uroperitoneum, bile, or bowel contents), hemopericardium, hemothorax, or pneumothorax. Typically, fluid in the peritoneum, pericardium, and pleural cavity is anechoic, but it can have echogenicity with clotting, depending on the age of the clot. Compared with other fluid-filled structures in the abdomen and pelvis, peritoneal free fluid generally has sharp edges and an irregular shape, whereas most visceral or vascular structures have intrinsically smooth oval contours and less abrupt edge detail.

The FAST technique uses a low- to middle-frequency probe (2–5 MHz) to evaluate dependent peritoneal spaces, pleural spaces, and the pericardium. Within the peritoneum, dependent spaces include the following, grouped by tissue window: right flank—this evaluates the hepatorenal space, also called Morison’s pouch (Fig. 197-1), the right subphrenic space, and the right costophrenic angle; left flank—this evaluates the splenorenal space between the diaphragm and spleen, the splenorenal space, the perirenal space, and the left subphrenic space; and suprapubic—this view is performed by placing the transducer superior to the pubic bone with a full bladder to visualize the pouch of Douglas in females and the retrovesical space in men. Extra views include the para-

![Figure 197-1. Free fluid in the peritoneum in Morison's pouch seen from right flank.](image)
injuries can be observed or treated nonoperatively with angiography. In obstetric patients, the few observational studies that have been performed have shown reasonable sensitivity and specificity, although abruption and fetal viability may necessitate an earlier operative course.

In patients with pelvic fractures, there have been mixed results, with sensitivity from 20 to 80%. More important, the detection of free fluid in an unstable patient with a pelvic fracture may be due to uroperitoneum from bladder injury rather than hemoperitoneum from vascular injury, clouding the decision for laparotomy versus pelvic embolization. In addition, retroperitoneal injuries to the genitourinary tract are not assessed with four-quadrant FAST exam.

**Pelvic Ultrasound**

Pelvic US by emergency physicians was initiated to address one of the epidemics of the modern era—ectopic pregnancy. Typically, pelvic US is used to confirm intrauterine pregnancy, thereby indirectly excluding ectopic pregnancy in the vast majority of patients. Other uses during pregnancy include detection of fetal viability, incomplete abortion, ectopic pregnancy, and molar pregnancy. Nonpregnancy pelvic US uses include the detection of tubo-ovarian abscesses, masses, and hemoperitoneum in the hemodynamically unstable patient.

Indications for sonographic evaluation of the first-trimester pregnant patient include symptoms or signs that suggest an ectopic pregnancy, molar pregnancy, fetal demise, or for dating the pregnancy. Standard definitions for intrauterine pregnancy describe a gestational sac with a yolk sac or fetal pole within the fundus of the uterus (Fig. 197-2). An embryonic or fetal demise has US findings of a fetal pole greater than 5 mm without fetal heart rate or a gestational sac greater than 20 mm in diameter without a fetal pole. A molar pregnancy appears as an echogenic, cystic uterus with disorganized echoes and is associated with high β-hCG concentrations without the sonographic finding of intrauterine pregnancy. Findings of an ectopic pregnancy include a chorionic ring or gestational sac with evidence of a yolk sac or fetal pole outside the uterus or in an abnormal location in the uterus, such as the cornu or cervix. Excluding the groups of IUP, embryonic demise, molar pregnancy, and ectopic pregnancy, there is a class called "indeterminate," which may account for 20% of pregnant patients presenting to the ED in the first and early second trimesters. Heterotopic pregnancies can occur at a rate of 1/5000 and be detected by the same techniques and definitions.

Pelvic US is performed by either transabdominal or endovaginal techniques. The transabdominal technique utilizes a low-frequency transabdominal transducer placed over the lower abdomen suprapubically. Ideally, the patient has a full bladder, which provides a sonographic window, but this may not be necessary if the uterus is large or the patient is thin. Advantages of the transabdominal technique include wider field of view, detection of large pelvic masses, and greater depth of field. In the endovaginal technique, the transducer is placed in the vagina, optimally with an empty bladder to visualize the same structures. Endovaginal transducers are high frequency, providing excellent axial resolution but poor penetration of distant structures. Early intrauterine yolk sacs and fetal poles within gestational sacs may be detected more clearly, and ectopic pregnancies can be identified with more accuracy. Endovaginal US can detect small (7 mL) amounts of peritoneal fluid. Endovaginal US in the hemodynamically compromised patient has replaced culdocentesis for detection of ruptured ectopic pregnancy.

Emergency physician-performed pelvic US has reduced the morbidity of ectopic pregnancy by shortening the time to diagnosis and operating room treatment, and it has resulted in greater initial detection of abnormal pregnancy, reduced emergency department patient throughput times, and increased patient satisfaction with emergency department care. Pelvic US in nonpregnancy states has shown good accuracy for tubo-ovarian abscess and improved decision-making for female patients with right lower abdominal pain.

**Cardiac Ultrasound**

The use of cardiac US by emergency physicians is presentation and symptom specific and focused in nature. Indications include cardiac arrest, possible pericardial effusion, trauma, chest pain, hypotension, and for procedural guidance. Cardiac US is often combined with other applications to form algorithms and protocols for certain symptoms or signs, such as dyspnea or hypotension.

Cardiac US is performed through the transthoracic and transabdominal windows using small curvilinear or phased transducers. Typical views include the subcostal four-chamber and long-axis views, parasternal long-axis view, parasternal short-axis view, and apical four-chamber view. Although most emergency physicians are very comfortable with the subcostal view from the FAST exam, the parasternal long-axis view is a good alternative and good window for left ventricular assessment. In addition, the apical four-chamber view provides excellent comparison of the right and left ventricles in terms of size and function.

Cardiac US performed by emergency physicians shows good accuracy in detection of pericardial effusion (Fig. 197-2),...
assessment of left ventricular function, and evaluation of patients with undifferentiated shock. In addition, aspects of cardiac US are being used for the assessment of intravascular volume status, cardiac output, and in the evaluation of dyspnea.

In cardiac arrest, US detects ventricular motion in both asystole and pulseless electrical activity (PEA). In asystole, two studies have shown poor prognosis in the absence of sonographic ventricular activity. Use of cardiac US in PEA and near-PEA states can be diagnostic for pericardial effusion. Cardiac US can detect pseudo-asystole by revealing ventricular fibrillation or coordinated cardiac contractions without a palpable pulse. Cardiac US can detect ventricular capture when the patient is paced, transcutaneously or by a transvenous pacer. It can also identify pneumothorax, another treatable cause of cardiac arrest.

Emergency cardiac US is diagnostic for detection of both medical and traumatic pericardial effusions. In patients with dyspnea, pericardial effusion is detected with excellent accuracy. In trauma, use of cardiac US reduces time to operative intervention and reduces mortality in patients with penetrating cardiac injury. Detection of effusions in blunt trauma has also been described. Patients with cardiac US performed by emergency physicians for pericardial effusion have significantly reduced hospital length of stay and charges.

Cardiac US is used for detection of pericardial effusions, chamber enlargement, and global activity in chest pain syndromes. In chest pain, US has been studied for the evaluation of pericardial tamponade, pulmonary embolus, cardiogenic shock, aortic dissection, pneumothorax, and bony chest wall fracture.

US protocols have been developed to evaluate patients with undifferentiated hypotension. Cardiac US windows with the addition of abdominal views can assess for effusion, global ventricular activity, ventricular chamber size, inferior vena cava (IVC) size and respiratory change, peritoneal fluid, and abdominal aortic aneurysm. Such a combined US protocol rapidly narrows the differential diagnosis. Sepsis is the most common diagnosis for patients with hyperdynamic ventricular activity.

Central pressures can be estimated by examining the IVC size and collapsibility. Several studies show that this technique has good accuracy in assessing blood loss and as a marker of hypovolemia. Correlation studies have shown moderate agreement between CVP and IVC measurements, with actual cardiac qualitative assessment as good as or better than the IVC measurements.

Cardiac US is also a procedural guide for placement of transvenous pacer wires and for pericardiocentesis. Transvenous pacer wires are often placed through central veins, and placing them into the right ventricular apex can be difficult. US facilitates placement by imaging the wires in real time as they pass through the tricuspid valve and approach the apex of the right ventricle. US can also document ventricular capture. The probe is placed in the subxiphoid space for both applications.

Abdominal Vascular Ultrasound

Abdominal aortic aneurysm is another silent disease for which US has been used by emergency physicians for diagnosis and management of patients with flank, abdominal, or back pain and for evaluating unexplained hypotension in the older patient. The use of US to detect aortic dissection in the chest and the abdomen has been described but is not common.

The technique involves imaging of the aorta from the subxiphoid space to the umbilicus to evaluate for dilation above a diameter of 3 cm (Fig. 197-4). Due to the increased incidence of infrarenal aneurysm, the technique must visualize the aorta from diaphragm to the aortic bifurcation. Fusiform aneurysms are more common, but saccular aneurysms can also be present, necessitating imaging in both the transverse and longitudinal planes. If an aneurysm is found, a peritoneal view of Morison’s pouch is performed to detect intraperitoneal fluid.

Emergency physician use of US for AAA detection has shown good accuracy compared to other imaging modalities and laparotomy. It also has management implications in older patients with lower back pain, where elimination of the presence of AAA can lead to other management decisions. Screening for AAA in the emergency department with US has been shown to be effective.

Aortic dissection may be detected by a combination of abdominal and cardiac scanning. Anywhere in the aorta, a linear echogenic flap across the lumen of the aorta is suggestive of dissection, with color Doppler possibly detecting different flows on either side of the flap. The cardiac US signs include unexplained pericardial effusion; a dilated aortic root; aortic insufficiency; and a linear echogenic flap seen in the ascending aorta, aortic arch (via a supersternal notch), or descending aorta.

Biliary Ultrasound

Biliary US to detect gallstones and associated cholecystitis was one of the early applications in emergency medicine. The sonographic technique involves a modified biplanar approach to the right upper quadrant to evaluate the gallbladder and surrounding area. A complete evaluation includes visualizing the common bile duct. The diagnosis of cholelithiasis is made after identification of echogenic foci within the gallbladder lumen with shadowing (Fig. 197-5). Other image patterns include stones that will not shadow, sludge, and the wall echo sign of a gallbladder full of gallstones. Signs of cholecystitis include a dilated gallbladder, increased gallbladder wall thickness, sonographic Murphy’s sign, and pericholecystic fluid. A nonmobile stone in the gallbladder neck is highly suggestive of eventual cholecystitis. A common bile duct
greater than 6 mm in people younger than 60 years and less than 10 mm in elders may indicate choledocholithiasis. Biliary US has been shown to be fast and accurate, with a sensitivity of 94% and a specificity of 96% in detecting gallstones.\textsuperscript{110,114,115} Biliary US has a primary role compared to nuclear medicine testing.\textsuperscript{112}

**Renal Ultrasound**

Renal or urinary tract US is one of the early applications for the diagnosis of urinary obstruction, resulting in hydronephrosis. The lack of ionizing radiation and the rapidity of renal US make it an attractive option for the investigation of unexplained flank, back, or groin pain.

The performance of renal US includes biplanar views of the kidneys with emphasis on dilation of the calyceal system and pelvis of the respective kidney. In addition, visualization of the bladder can diagnose secondary hydronephrosis from an obstructed bladder stone and may demonstrate nonobstructive bladder jets through the use of Doppler US. The windows for the two kidneys are very similar to the trauma flank series with the exception that the patient may be rolled on the opposite side so that the transducer may be placed more posteriorly on the back if needed. The bladder view is performed suprapubically, and calculations of volume may be made with on-machine calculators or by formulas.

Renal US has a sensitivity of 83% and a specificity of 92% in detecting hydronephrosis (Fig. 197-6).\textsuperscript{116,117} Genitourinary tract obstruction protocols have shown great sensitivity in eliminating renal obstruction from a differential diagnosis.\textsuperscript{118} Bladder US is useful for detection of a full bladder and the presence of a Foley catheter and also for procedure guidance (superpubic aspiration or Foley placement).\textsuperscript{119-124}

**Extremity Vascular Ultrasound**

The swollen extremity often requires sonographic imaging to assess for DVT. Emergency physicians commonly utilize compression US to rule out DVT.\textsuperscript{125-128} The two-level compression technique involves visualizing the compressibility of the common femoral and popliteal veins, whereas the three-level technique adds visualization of the compressibility of the junction of the superficial femoral and deep femoral veins (Figs. 197-7 and 197-8). Upper extremity veins have been investigated, but this is not a common application because Doppler is needed for sampling of the subclavian vein, which is not compressible under the clavicle.\textsuperscript{129}
The accuracy of this technique ranges from 70 to 99%, depending on operator experience.130,131 Hospital charges and time in the emergency department are reduced for patients who have venous US performed by emergency physicians to rule out DVT.132,133

Thoracic and Tracheal Ultrasound

Thoracic applications include the detection of pleural effusion, pneumothorax, as well as other pathologic lung states. The technique of thoracic US utilizes a low-frequency probe to survey for pleural effusions and a high-frequency probe to detect pleural lines and related artifacts. Pleural fluid appears as an anechoic collection above the diaphragm. In addition, the lung may be collapsed and visualized as an echogenic floating structure. Normally, the parietal and visceral pleural lines slide against each other, and lack of sliding is the finding most consistent with pneumothorax.134,135 Confounding factors include adhesions of the pleura, chronic obstructive pulmonary disease, and prior pneumothorax. A lung point sign is the edge of the pneumothorax where the lung is still adherent to the parietal pleura, and part of the image shows no sliding until the lung moves into the interspace with respirations.136 The accuracy of US for detection of pneumothorax is better than that of plain chest x-ray in the acute setting, but there are concerns regarding reduced accuracy after 24 hours.137-139

Severe pneumonia is visualized as echogenic “liver-like” echogenicity as the lung accumulates fluid with consolidation. Peripneumonic collections are common and may indicate inflammation.

Pulmonary edema is indicated by the presence of comet tails, which are reverberation artifacts that reflect from the parietal pleural interface into the lung. Normally found in dependent areas of the lung, the widespread distribution of these artifacts in an apical lung may indicate increased lung congestion.140,141

Tracheal US has been explored for the confirmation of endotracheal intubation with relatively good sensitivity and specificity.142,143 The dynamic movement of the endotracheal tube creates a flutter through the recognized shadow of the airway, but static US seems to lack accuracy.144,145 This technique may have a role in patients in cardiac arrest or with equivocal end-tidal carbon dioxide, and it has been used in pediatric patients with significant decreased time to confirmation compared with chest radiography.146

Ocular Ultrasound

Ocular US has been described for intraocular pathology such as retinal detachment, retinal hemorrhage, vitreous hemorrhage, intraocular foreign body, dislocated lens, and retro-orbital hemorrhage.147 The eye is an excellent acoustic window, and short-duration gray scale US over a closed eyelid can visualize both the anterior and the posterior chamber well. In addition, the optic nerve sheath diameter can be measured behind the eye, reflecting intracranial pressure.147-149

Soft Tissue Ultrasound

US in soft tissue is facilitated due to the lack of air and bone in the skin and subcutaneous tissue except in the hand and foot. Soft tissue US is used to differentiate cellulitis from abscess, for detection of foreign bodies and hernia, and for the evaluation of other soft tissue pathology.140,147,150 The technique involves the use of a high-frequency linear transducer to image the soft tissue from normal skin to the abnormal area. Cellulitis or edema will cause an echogenic pattern with cobblestoning between fat lobules. Abscesses are irregular hypoechoic to anechoic collections within the subcutaneous layer but may connect with the surface. US is diagnostic in soft tissue disease states such as cellulitis, abscess, and necrotizing fasciitis.150-153 In the ABSCESS study, clinical exam had a sensitivity of 86% and specificity of 70%, whereas US had a sensitivity of 98% and specificity of 88%. Management in half of the patients with clinical cellulitis was changed based on results of US.27

US can detect peritonsillar abscess with differentiation of cellulitis versus abscess, and it can be used for guidance of peritonsillar aspiration.154 It can also detect early Ludwig’s angina with abscess in the soft tissues and fascia of the face.155

Detection of foreign bodies is characterized by variable echogenicity in the tissue with unexpected shadowing beneath the foreign body. Metal foreign bodies may have characteristic highly reflective echogenicity and ring-down artifacts. Bedside US has had variable accuracy for detection of foreign bodies in simulated cases but better accuracy in clinical settings.156-158 Use of a water bath may aid the detection of superficial foreign bodies.159

Musculoskeletal Ultrasound

The use of US for musculoskeletal disorders is focused on joint effusion and fractures. US is excellent for detecting fluid in joints and confirming effusions and guiding drainage procedures.159,160,161 Joint effusions typically are anechoic or echogenic, depending on type and age. Diagnosis of ligamentous injuries and muscular avulsion and hemorrhage has also been reported.162-164 Muscular and tendon abnormalities are detected by anechoic and heterogeneous abnormalities. Detection is often assisted by movement of the limb. Tendons and their anastrophic longitudinal fibrils can be visualized near joints, with pathologic tears appearing as a discontinuity of the tendon. Muscles are hypoechoic with echogenic borders. Tears or hemorrhage may be seen as interruption of this normal pattern.164 Water bath techniques provide a better acoustic window for very shallow tissue such as fingers.

In addition, the characteristic reflection of bone with immediate shadowing can be used to visualize normal bone and its contour. Detection of fractures requires identification of a defect in the bony cortex.165-167,168 The ability to image the bony cortex can be useful for guidance of fracture reduction.167 Comparison with the contralateral side may also be helpful.

US is accurate in the detection of fractures, joint effusions, and hematomas.169-172 Prospective evaluation of finger fractures demonstrates good accuracy.169 Other fractures studied include femur, sternal fracture, rib fracture, and forearm fractures.170

US is also used to guide anesthetic blocks and hematoma blocks.170-172

Transcranial Doppler Ultrasound

Transcranial Doppler US has been used by some emergency physicians for detection of abnormal flow patterns in the brain and for detection and treatment of middle cerebral artery strokes. An advanced procedure, typically using a phased array transducer over a bone or orbital window in the skull, color Doppler and spectral Doppler scanning is performed at different levels of intracranial vessels for detection of abnormal patterns.173

Testicular Ultrasound

Testicular scanning is an advanced US application that requires visualization of the normal and symptomatic testicle using a
high-frequency probe. The normal testicular structures, including the normal homogeneity of the testicle, are evaluated, and Doppler scanning is performed for evaluation of normal venous and arterial flow. Absence or a difference in flow from the unaffected side indicates possible torsion, whereas increased flow indicates epididymitis. Experienced emergency physicians accurately diagnosed testicular pain with a sensitivity of 95% and specificity of 94% in a study of 36 patients, which included 3 patients with torsion.174

**Abdominal Bowel Ultrasound**

The use of bedside US for evaluation of appendicitis, diverticulitis, and other bowel pathology is an area of increasing interest. There has been variable experience with the use of graded compression US to detect appendicitis, with reported sensitivity of 67% and specificity of 92%.175 The novel use of US to detect diverticular disease and hernias has been described.176,177

**Ultrasound for Procedural Guidance**

In 2001, in response to the Institute of Medicine report “To Err Is Human,” the Agency for Healthcare Research and Quality (AHRQ) sanctioned a report on actions that may improve patient safety.178 The report contains a recommendation for US guidance for internal jugular central line insertion. Since then, the use of US for procedural guidance has expanded for almost every known emergency procedure, but especially vascular access.

There are several key concepts regarding procedural guidance with US. Procedural guidance can be static or dynamic.179 Static guidance suggests that US has been placed over the anatomic area, and the area is marked while angle and distance information is noted. Dynamic guidance describes procedures performed with real-time US visualization of the needle entering the anatomic area.

There are two approaches to vein cannulation: transverse, where the vein appears as a circular structure on the screen, and longitudinal, where the vein appears as a tubular structure along the width of the screen. In the transverse approach, the probe’s long axis is centered transverse (90 degrees) to the long axis of the anatomic area, guiding the needle to bisect the probe at its center giving centering and depth information. In the longitudinal axis, the probe is placed along the long axis of the anatomic area, and the needle is introduced in the long axis of the probe, giving depth and trajectory information.

US guidance for central line insertion has been the most studied application and most advocated use among US-guided procedures.180-182 Both the AHRQ and the National Institute for Health and Clinical Excellence have recommended US guidance for central line insertion.183,184 US guidance for internal jugular (IJ) central line insertion can be recommended as a best practice and safe practice.180,185

US permits the physician to assess the IJ for overlap with the carotid artery, vessel diameter, and the presence of luminal clot or vessel obliteration.186 IJ central line insertion has been studied in the emergency department, intensive care unit, and radiology suite. In the emergency department, there is decreased time to flashback and improved success in the difficult stick patient and improved overall success rate, first attempt rate, reduced time to insertion, and reduced complication rate with US guidance for IJ cannulation.

Femoral vein insertion has been studied in cardiac arrest patients, and improved cannulation rate and reduced complications have been reported.187 Several maneuvers can optimize the success rate of femoral vein cannulation, including reverse Trendelenburg position and placing pressure on the iliac vein proximal to the femoral vein.188

Studies of US-guided subclavian insertion suggest that US does not contribute to procedural success because of a lack of a convenient window for the subclavian vein. At the location where the vein is usually cannulated, visualization is obstructed by the clavicle. However, more laterally, toward the junction of the axillary vein and subclavian veins, the vein can be visualized in the chest wall.189,190 Although it may be cannulated there, the more difficult challenge may be inserting the catheter through the pliable soft tissue of the anterior-superior chest.191 The supraclavicular fossa is a window for central line insertion, and the subclavian and brachiocephalic veins may be imaged from this site.192

Emergency physicians are able to use US to insert peripheral intravascular catheters in difficult patients with high success rates.193-195 Nurses have also been taught to use US for peripheral venous guidance.196,197

Arterial access, including radial artery aspiration and cannulation, is more successful with the use of US guidance.198,199

Numerous other procedures using US guidance have been described in emergency practice. They are listed in Table 197-2.

Out-of-Hospital Ultrasound: Disasters and Remote Settings

US has been used in various settings, including out-of-hospital, the military battlefield, disaster settings, critical care settings, and international medicine settings. The use of US has been described in European and other settings that utilize physicians in the out-of-hospital arena, including ground, helicopter, air, and space.\(^9,200-204\)

The military was a source of funding for small compact US machines and has been an extensive user of US in combat situations, including the frontline, combat support hospital, and tertiary hospital settings.\(^8,205,206\)

US in disaster and other mass casualty situations has been described, including their use during the Armenian earthquake of 1988. With smaller, more compact machines, US capability may become part of disaster facilities and plans.\(^207\)

INTEGRATION INTO EMERGENCY MEDICINE PRACTICE

US technology has rapidly been integrated into emergency medicine practice due to the need for effective, noninvasive, nonpainful, portable imaging techniques.\(^208\) US, whether introduced in medical school, residency, or clinical practice, is a skill that requires constant attention with hands-on practice and interpretation.\(^15,209\) However, with the integration of US into emergency medicine practice, emergency care has become more rapid, efficient, safe, and accurate.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Every day, in emergency departments throughout the United States, physicians encounter challenging cases that require an appreciation of cultural differences. Lack of understanding of the role of cultural factors can have an adverse effect on physician-patient communication and trust. Health outcomes can also be negatively affected, as demonstrated by a large body of literature on racial and ethnic disparities in types of interventions and outcomes for heart and lung disease. Race, culture, ethnicity, class, gender, economic conditions, spirituality, and sexual orientation define health and illness for patients and affect both access to health care and the quality of services received. Missing these cues may lead to medical errors.1,2

The American College of Emergency Physicians (ACEP) Code of Ethics, 1998–99, commits emergency physicians to “protect the rights and best interests of the most vulnerable … [and] secure access to emergency and other basic health care for all.”3 This code also recognizes that “denial of emergency care or delay in providing emergency services on the basis of race, religion, ethnic background, social status, type of illness or injury, or ability to pay is unethical.” Lewis Goldfrank, past president of the Society of Academic Emergency Medicine (SAEM) and a member of the Institute of Medicine, and Robert Knopp, Deputy Editor of Annals of Emergency Medicine, comment in an editorial about ethnic disparities in emergency department analgesia prescription:

With the legacy of racism and the growing body of medical evidence indicating differential care in the emergency department and other medical specialties, we believe that the burden of responsibility has now shifted so that the medical profession must now demonstrate that physicians are providing appropriate and timely care for all. “Our integrity must now be questioned. ... Our integrity as a profession and as a nation hangs in the balance.”

The purpose of this chapter is to provide the knowledge base in cultural competence that is essential to meet patient needs, improve health outcomes, reduce racial and ethnic disparities, and achieve professional goals.

**RATIONALE FOR CULTURAL COMPETENCE**

**Changing Demographics: New Challenges for Emergency Physicians**

We live in a global community, and both the U.S. population and the types of health problems seen by emergency physicians are constantly changing. In 2000, the U.S. Census Bureau estimated that 12% of the U.S. population was foreign born and 20% spoke a language other than English at home.4 It is projected that by 2030 the proportion of Hispanics will increase from 13 to 20%, and racial and ethnic minority representation in the United States will exceed 40%.5

These figures do not speak to the diversity within these groups. The category Hispanic, for example, is an ethnic grouping counted in the race category of the census, but it fails to capture the significant range of diversity represented by Spanish speakers. Hispanics may share some cultural practices and speak similar versions of the Spanish language but have major differences in vocabulary, history, socioeconomic status, cultural identity, what they call themselves (Hispanic or Latino), levels of acculturation, health beliefs, habits, access to care, and health outcomes.

What do these changes in demographics mean to practicing emergency physicians? The ACEP Code of Ethics challenges us to recognize ethnic and racial differences in health care access and outcomes, to advocate for equity, and to work with other health organizations and providers to contribute to eliminating these disparities.

**Racial and Ethnic Disparities in Health Care Access and Outcomes**

In the past decade, both financial and nonfinancial barriers to access for racial and ethnic minority populations have been thoroughly documented. These include high rates of uninsurance, lack of prenatal care, hospitalizations for ambulatory-sensitive diagnoses (an indicator of reduced access to primary care), and concentration of minorities in areas of physician shortage.6 In 2003, the Institute of Medicine (IOM) produced a report commissioned by the U.S. Congress in which more than 100 studies assessing the quality of care for racial and ethnic minority populations in the United States were analyzed.7 According to the IOM report, minorities received fewer needed services and procedures than whites, after controlling for insurance status, income, and other access factors. These findings applied to a wide range of health conditions, such as cancer, cardiovascular disease, HIV/AIDS, diabetes, and mental illness. The findings identified cultural and linguistic barriers, fragmentation of the health care system, and differences in sites of care delivery and insurance coverage as explanatory factors. The authors suggest that unconscious bias, prejudice, stereotyping, and physician uncertainty of severity may influence clinical decision-making and allocation of services and procedures. Patient preferences may account for some of the range of distribution of services, but preference alone is insufficient to explain health care disparities. The report concludes that “racial and ethnic disparities in health care exist, and...
because they are associated with worse outcomes in many cases, they are unacceptable.”

The IOM report also discussed important nonfinancial barriers to access, such as the unequal distribution of physicians in areas where minority populations live. In particular, the number of racial and ethnic minorities living in medically underserved areas is three times the proportion of minorities in the general population. Poor urban communities with high African American and Hispanic representation averaged 24 physicians per 100,000 people compared with 69 physicians per 100,000 in communities with low representation. Although minority physicians are more likely to serve patients with Medicaid or no insurance, enrollment of minorities in health profession schools has been declining for African Americans, Hispanics, American Indians, and Alaskan Natives. In fact, the American Association of Medical Colleges (AAMC) reported that in four states with restrictions against affirmative action, in the year following enactment, there was a 17% decline in applications and a 26% decline in matriculation to medical schools from underrepresented minority groups. A survey conducted in 1997 by the SAEM Task Force on Women and Minorities found that 59% of residency-affiliated sites had no minority faculty member. Dr. Jordan Cohen, president of AAMC, argues that “to achieve diversity in the health profession is not someone else’s problem; it is a problem for the profession, for all of us who are concerned about the future of access to health care and the quality of health care that we are going to be able to provide our society.”

The National Institutes of Health National Center for Minority Health and Health Disparities, created by Congressional Public Law 106-525 to oversee research in health care disparities, reports that improvements in health have not been universal during the past two decades: “Striking disparities in the burden of illness and death” exist for African Americans, Hispanics, Native Americans, Alaskan Natives, Asians, and Pacific Islanders. Despite a decade of attention focused on racial and ethnic health care disparities, progress in narrowing critical gaps in life expectancy has been slow. Life expectancy for blacks as a whole is 73.2 years versus 78.3 years for the white population—a gap of 5.1 years. For black males versus white males, the gap is even larger (6.2 years). Lower life expectancy for blacks is accompanied by higher rates of cardiovascular disease, cancer, infant mortality, maternal mortality, birth defects, asthma, diabetes, stroke, intentional injury inflicted by others, sexually transmitted disease, and mental illness. The reliability of data for Hispanics is limited by inaccurate reporting of race/ethnicity on birth and death certificates, the healthy migrant effect, and the possibility that migrants may return to their country of origin when they become ill or disabled.

Factors Contributing to Disparities in Health Outcomes

In the past decade, reports have been regularly published in major peer-reviewed journals about disparities in the use of diagnostic tests and procedures, access to appropriate treatment modalities, and waiting times to receive care in emergency departments.

Test and Treatment Options: Physician-Patient Communication Failure?

Studies document clearly that both Hispanics and African Americans receive fewer analgesics for extremity fractures and for musculoskeletal pain than white patients in the emergency department setting, despite no evidence of difference across race and ethnicity in the ability to discriminate painful sensation. In secondary analyses of the National Hospital Ambulatory Medical Care Survey data for 1993 to 2005, opioids were less likely to be prescribed to African Americans (23%) and Hispanics (24%) for pain relief than whites (31%), and these differences were greatest for patients with the most severe pain. Disparities in emergency department pain treatment continue to persist a decade after identification of racial and ethnic differences in analgesic administration.

Evidence from other specialties corroborates that differences in provision of medically appropriate procedures and therapies are often related to race and ethnicity. In the case of preventive measures, for example, elderly African Americans and Hispanics are less likely to receive influenza and pneumococcal vaccine, and Hispanics are less likely to have a blood pressure check or a cholesterol level within the past 2 years.

In the domain of surgery, the operative rate for certain lung cancers was 76.7% for whites and 64% for African Americans, and the 5-year survival was 34.1 and 26.4%, respectively. The authors concluded that if blacks had undergone surgery, the 5-year survival rate would have been similar. An accompanying editorial suggests that the medical establishment take some responsibility for the racial discrimination that results in inadequate emphasis on prevention or insufficiently aggressive care for African Americans.

These issues also apply to disparities between black and white populations with respect to cardiovascular disease. After adjusting for severity and coexisting conditions, African Americans are less likely to undergo either angioplasty or bypass surgery than whites, and differences are more significant for those predicted to benefit most from revascularization. A multicenter emergency department study found racial disparities in access to cardiac catheterization for African Americans and other non-whites with acute myocardial infarction and unstable angina. The researchers also found that African American patients were less likely to receive a timely electrocardiogram or an assay for cardiac markers, and doctors were less likely to prescribe anti-ischemic medications.

In recent years, racial and ethnic disparities in emergency department treatment decisions have also been identified for admission following a diagnosis of pancreatitis, for care related to mild traumatic brain injury, and headache, for rate of appendicitis rupture, and for underdiagnosis of psychiatric disease.

Discrimination and Health Outcomes

Deleterious health consequences that result from racial discrimination have been well documented. In a study of the nation by state, in states where more respondents to the General Social Survey indicated that blacks lacked innate ability, there was a closely associated increase in age-adjusted black mortality that was considerably stronger than the correlation for mortality and socioeconomic status. Mechanisms used to cope with the stress of racism have been shown to backfire by adding to health risks, as in the case of smoking, substance abuse, and overeating. Racism-induced stress has been shown to be negatively associated with disease entities such as diabetes, hypertension, depression, and preterm birth. Similar experiences have been described for homosexuals vis-à-vis homophobia.

Race-Based Medical Decision-Making

Racism, sexism, and homophobia can interfere with the establishment of trust and the delivery of effective medical care if providers create or establish barriers based on their own
Failure of Trust

Patients from minority communities have reason to be skeptical about the validity of medical research and the appropriateness of medical recommendations. Participants in the Tuskegee study, for example, were not notified when effective treatment for syphilis became available because researchers wished to investigate the natural course of the disease. Middle-class African American patients often rate their physician interactions as less participatory than when the doctor is of the same race as the patient. Yet this option for physician-patient congruence is rarely available to minority patients because only 4% of physicians are black, whereas 12% of the population is black.

In the Agency for Health Quality Research National Healthcare Disparities Report, blacks and Hispanics were found to be more critical of the patient-provider relationship than were whites. A higher percentage of adult blacks and Hispanics rated their health care at less than 6 on a scale of 1 to 10 in the past year and believed that they would have received better care if they were of a different race or ethnicity. The report provided evidence confirming perceptions of a lower quality of medical care. For example, when black and Hispanic adults older than 65 years were hospitalized for pneumonia, they were less likely than comparable whites to have blood culture samples drawn and antibiotics administered in accordance with current recommendations. Hispanics with myocardial infarction were less likely to receive aspirin or a beta-blocker on admission and discharge. In comparison to white dialysis patients, fewer blacks and Hispanics in need of a kidney were registered on waiting lists for transplant or had received a transplant within 3 years.

Language and Effective Medical Care

According to the 2000 U.S. census, 47 million Americans (18%) speak a language other than English at home, 21.3 million speak English less than very well, and 10.7 million speak English not at all or not well. Patients with limited English proficiency are more likely to defer needed services, leave against medical advice, miss appointments, fail to adhere to treatment regimens, lack a regular provider, and report poorer health status.

Transcribed audiotapes of medical encounters in a pediatric emergency department setting were studied to ascertain differences in communication error rates for patients who were aided by professional hospital interpreters compared with those who had an ad hoc interpreter (e.g., family, friend, or nonprofessional hospital worker) and those who had no interpreter available. They found that communication errors occurred equally among the ad hoc and the no interpreter groups. These errors included left out words (52%), incorrect words (16%), substituted words (13%), interjected personal views (10%), and added words (8%). The errors of ad hoc interpreters were more likely to result in clinically significant medical errors, such as omitting drug allergies and giving inaccurate instructions on dosing and route of administration.

The use of untrained nonprofessional employees as interpreters resulted in serious translation errors, including omissions, additions, and substitutions for what the patient is trying to say, and the use of relatives, particularly children, may violate privacy and disrupt family norms of authority.

A cross-sectional survey at a public hospital emergency department suggested that there is a patient-perceived need for interpreter services, and the highest patient satisfaction ratings are obtained when patients can communicate directly with their physicians. Satisfaction ratings for patients using ad hoc interpreters are lower, and rates are lowest when an interpreter should have been used but was unavailable. In one retrospective study of Spanish-, Haitian Creole-, and Portuguese Creole-speaking patients presenting to the emergency department with chest pain, headache, and abdominal pain, the investigators found that the use of trained interpreters was associated with increased intensity of emergency department services, reduced emergency department return rate, increased clinic utilization, and lower charges during the next 30 days, without any simultaneous increase in length of stay or cost of visit.

A statewide emergency department patient satisfaction survey in Massachusetts indicated that non-English speakers were less satisfied with their emergency department care, were less willing to return for care, and reported more problems with emergency care. The authors state that interpreter service is likely to improve the satisfaction of this group.

Evolution of New Standards for Health Care

In response to the identification of unacceptable differences in both health care provision and health care outcomes, state Medicaid regulations and Health Plan Employer Data and Information Set criteria now reflect the need to establish quality performance measures to ensure access to appropriate services for culturally diverse populations. A new standard of care has been established that requires institutions and practitioners to provide for medical needs in the patient’s primary language and in a manner compatible with patients’ health beliefs and practices. Health care institutions and providers are asked to collect data stratified by race, ethnicity, and language and to institute quality improvement efforts when cross-cultural differences in outcomes of care, process indicators, or patient satisfaction are detected. They are asked to develop culturally competent systems of care based on an assessment of the organization’s mission, goals, policies, practices and services, staff training needs, and the current diversity of the staff.

After the assessment process, health care organizations must identify opportunities to improve the cultural competence of the organization and its delivery of health care services to a diverse population. At the top of the list is the improvement of interpreter services. Hospitals are asked to establish minimum performance standards for interpreters that include training in culturally specific medical language and code of ethics. These requirements have been codified as a set of standards for culturally and linguistically appropriate services (CLAS Standards) by the Office of Minority Health and the Agency for Health Care Research and Quality and published in the Federal Register (December 15, 2000). In spring 2000, the Massachusetts legislature took a positive step in the
direction of compliance with these standards by passing a law requiring all emergency departments to provide interpreter service and authorizing the state to provide Medicaid reimbursement for interpreter services.

Culturally Competent Approach to Language Barriers

In 1996, the SAEM Task Force on Physician-Patient Communication identified lack of a common language as the most common barrier to communication in the emergency department. Professional medical interpreters were recommended for the following reasons: (1) confidentiality, (2) medical knowledge and a common vocabulary with the provider, and (3) fluency. Two emergency department case reports illustrate this point.

A 50-year-old Mexican American man who spoke only Spanish was seen in the emergency department because of “chest pain.” Because no translator was available, an electrocardiogram and chest radiograph were ordered. The electrocardiogram was normal; the chest radiograph showed a widened mediastinum suggestive of a dissecting aortic aneurysm. An aortogram was subsequently performed, which demonstrated a normal aorta. At some point, a Spanish-speaking physician was able to elicit a 1-year history of difficulty swallowing and regurgitation of food. A barium swallow was performed, which revealed achalasia.

A 22-year-old Vietnamese man arrived in the emergency department unresponsive and comatose with small, reactive pupils. Naloxone hydrochloride and 50% dextrose in water were administered without response. The medical history was obtained from a family member who spoke some English. It consisted of brief answers to specific questions and was not helpful diagnostically. A lumbar puncture and examination of the cerebrospinal fluid ruled out meningitis. A clerk later recalled that a child with the same last name was admitted the previous day for headache, nausea, and vomiting caused by carbon monoxide poisoning. In retrospect, it was clear that the history obtained from a family member who was under stress and giving vague answers to pointed questions was inadequate. The authors conclude that “a trained bicultural translator can effectively elicit the history as conceptualized by the patient or family and translate it both linguistically and in the format of Western medicine.”

The previous example also illustrates that bilingualism is necessary but not sufficient. There are nuances and sociocultural assumptions in both languages as well as nonverbal cues that must be communicated along with words for effective diagnosis, treatment, and disposition. The medical interview is the heart of the medical encounter between physician and patient, yet in an interpreted interaction, neither patient nor physician is in a position to judge the accuracy or completeness of a lay interpreter’s translation. Clearly, omissions, additions, opinions, guesses, and distortions can lead to serious mistakes and unnecessary diagnostic procedures.

Standards and certification for medical interpreters are needed to ensure consistency and quality. The Massachusetts Medical Interpreter Association recommends that standards cover interpretation, the cultural interface, and ethical behavior. Because the meaning inherent in the message is rooted in culturally specific beliefs, values, assumptions, customs, and norms, and language is itself an expression of culture, it may be necessary for a medical interpreter to go beyond a literal interpretation to explain unstated assumptions and to find new ways of communicating untranslatable words or concepts. In addition to maintaining confidentiality, the medical interpreter has an ethical burden to uphold the trust of both parties and assure them that the considerable power associated with the interpreter’s role will not be abused and that information will be faithfully conveyed without interpreting the subjective opinions and thoughts of the interpreter. Even with such qualified interpreters, the emergency physician still needs to monitor the flow of the interview and, from time to time, clarify meaning and ensure understanding. This can be done by having the interpreter repeat what he or she thought the patient meant and asking the patient to repeat what the interpreter said. It is important to observe the interaction for phrase length as an indication of material not translated or added by the translator.

Using Cultural Competence to Cross the Barrier of Different Beliefs, Values, and Life Experiences

Both physicians and patients have a culture that they bring into the examining room. Differences between their cultures have an impact on the physician-patient encounter. Awareness of one’s own values and those of others can enhance both satisfaction and health outcomes. The SAEM task force report cautioned, however, that it is dangerous to hold strong preexisting assumptions about any cultural group because variations within cultures often exceed variations between them. A patient who is thoroughly acculturated into American society may be offended by a health care provider’s attribution of traditional beliefs. Even in the context of a busy emergency department encounter, it is necessary and feasible to get to know the individual patient sufficiently to make a rough assessment about level of acculturation, or at least to ask rather than to assume.

In some cultures, the diagnosis of specific diseases can be particularly problematic. For example, in African-American and Puerto Rican communities, cancer is often perceived as a fatal disease. Patients may therefore avoid initial evaluation or choose no treatment when diagnosed, even when the cancer is identified at an early stage and the prognosis is good. A health care provider who understands these health beliefs and concerns can work collaboratively with patients to provide health information in a format that the patient can accept.

Alternative healing systems have strong cultural roots. In 1997, the U.S. population made an estimated 629 million visits to providers of alternative health care—approximately 243 million more visits than to conventional health care providers and an increase of 47% since 1990. An estimated 44% used at least one complementary alternative therapy in 1997.

Folk medicine is too diverse for providers to know all possible practices, but emergency physicians need to know some of the more common therapies and ask their patients about them. For example, more than a few emergency physicians have called social workers to investigate children with apparent bruises caused by coinage, which involves vigorous rubbing of the skin with coins and warm oil (tiger balm) to release the “bad wind” (reduce fever). These parents, who have attempted to help their children by using health care practices that are widely accepted in their communities of origin, feel accused, and the trust between the physician and the family may be irrevocably lost. Similarly, herbal remedies can be effective or at least harmless, but occasionally they can be toxic, as in the case of clay ingestion by pregnant women, the use of marijuana tea to treat asthma, and powders containing high concentrations of lead oxide to treat empacho, a condition in which it is believed that a substance (usually food or saliva) gets “stuck” to the walls of the stomach or intestines, causing an obstruction. Specific uses of folk medicine need to be elicited respectfully in a careful history and evaluated. Recommendations can
then be presented nonjudgmentally, and alternative folk remedies that are benign can be prescribed along with needed allopathic medications.

The practitioner and the patient will inevitably bring different beliefs and values to the medical encounter; the key to cultural competence is respectful negotiation of these differences without imposing the power of physician expertise, thus protecting patient autonomy. If patients are satisfied, they will carry out follow-up recommendations and return to the emergency department in the future when they need emergency care.

In a review of Hispanic cultural practices, Flores suggests a five-step approach for the pediatric emergency department that is applicable to all emergency medicine: The physician should (1) explain that he or she is aware that a given folk illness exists; (2) ask whether the parent or patient has ever heard of it; (3) ask whether the patient has the folk illness now; (4) ask what treatment the patient is receiving for the condition; and (5) suggest alternatives to harmful folk remedies, accommodating wherever possible (nonjudgmentally) to folk illness beliefs and practices, and integrating the use of harmless folk remedies into the treatment plan when the patient so desires.73

Interpreting the Culture of Medicine to Patients from Diverse Backgrounds

There are inherent conflicts between the culture of medical care, particularly emergency department culture, and the cultures of many patients. Physicians are expert in diagnosing and treating diseases, which represent abnormal structures or functions of the human body (the pathophysiology of disease states). On the other hand, patients experience illness, a subjective, feeling state that is interpreted through the lens of culture and has a personal and social meaning. The patient is an expert in his or her own illness and its effects on daily living, whereas a physician is expert in the effects of diseases on organ systems. Both ways of looking at the world have validity, but they are radically different.74 Unfortunately, the culture of medicine tends to recognize only its own interpretation and perspective. A culturally competent approach recognizes both and works to integrate the best of both worlds.

A patient may have very high blood pressure, HIV, or early cervical cancer and not experience symptoms. If patients do not feel sick and experience no alteration in functioning, they may not accept a physician’s diagnosis. There may be conflict between the patient’s perception of causality and the physician’s, as in the case of the differences between the medical diagnosis of hypertension and the commonly accepted view of hypertension as “high blood” in the African American community.75

On the other hand, a patient may feel sick—be ill, weak, and dizzy, with extreme fatigue or abdominal pain—yet the physician is unable to diagnose a disease despite a thorough history, physical examination, testing, and appropriate consultation. For example, susto, an illness recognized by Mexican Americans, causes listlessness, insomnia, depression, and anorexia and is believed to be caused by exposure to a frightening experience. Treatment requires the patient to speak openly about the events that led to the susto, followed by bedrest and a ritual that includes prayers, incantations, and barridas (sweeping of the body with an egg, a candle, or herbal teas).76

To be most effective, physicians need to investigate how patients view the causality of their illnesses and how they experience them in order to negotiate a therapeutic intervention. Exploration might take the form of comments and questions such as, “Help me to see through your eyes how you understand this problem. Have you or someone you know experienced it before?” The role of the physician is to accept the patient’s experience as uniquely his or hers or, when possible, reframe it in terms of medical knowledge. Then both physician and patient will be satisfied with the outcome of the encounter.

Role Expectations in Western Medicine: Opportunity for Misunderstanding

The culture of medicine, especially in emergency medicine, has its own set of patient expectations, rules and regulations, language, and dress distinctions that reflect a hierarchy of authority, a characterization of patients as good or bad, and different sets of behaviors toward patients depending on the category to which they have been assigned. The “good emergency patient” is acutely ill but waits patiently until called without complaining, requesting pain medications, getting angry, or being loud or disruptive. The “good patient” understands the triage system and provides a clear, concise, pertinent history with enough information for accurate diagnosis. The “good patient” does not take up physician time with minor complaints, feelings, or tangentially related information. The “good patient” accepts invasive examinations and procedures without protest, agrees to admission or to a discharge plan, does not require long explanations of rationale for treatment, and has a support system in place for a safe discharge. A “good patient” who does not speak English brings someone to interpret, someone who can bridge the cultural divide and help with transportation upon discharge. A “good patient” does not moan, scream for a nurse or doctor, or act violently. A “good patient” does not have family members who are emotionally upset, stir up trouble, or challenge providers. A “good patient” uses seat belts, maintains personal hygiene and normal weight, takes prescribed medications, avoids drugs and cigarettes, and exercises. “Good patients” share a trust, understanding, and belief in scientific, modern, technological medicine and its value. Because they comprehend the physician’s explanation of causality—for instance, bacterial infection as a cause of pneumonia—they agree to a discharge plan and adhere to a treatment regimen. They understand medical jargon and require very little explanation and ask a minimum of questions. “Good patients” help maintain the flow through the emergency department, whereas their opposites obstruct the flow. “Good patients” get better; the “bad patient” keeps coming back, has chronic recurrent conditions, and has confusing or difficult to resolve problems.

Thus, it is not surprising and no fault of their own that people from different cultures may find it impossible not to violate one of the many rules and regulations of the emergency department. Every medical encounter is potentially a cross-cultural experience, and negotiating the divide is a challenge for both patients and providers. Cultural competence involves a reframing of many of these unstated rules because they prevent us from looking beneath the surface and addressing real problems. When a patient comes in with vague complaints, there may be a social stressor that has tipped the balance of mental health. There may be circumstances that the patient does not feel comfortable sharing with the provider because of cultural, racial, or language barriers, or there may have been an overload of negative stimuli related to racial and ethnic discrimination—a crisis for the person and the body this person inhabits.77,78 People from minority cultures experience stressful events daily that the white provider, secure in his or her socioeconomic status and membership in the dominant majority, can only imagine: being passed by the 15th taxi in a
row because “it’s not safe to pick up blacks”; being followed in a department store because you and your friend were speaking Spanish; having to “dress up” to go to the store to avoid a possible humiliating moment; or standing in line to register at a hotel, dressed in professional clothing, and being asked by a white person in line, “Hey, can you take my baggage to my room?” In each of these cases, assumptions were made about the person on the basis of a stereotype related to physical appearance or presumed country of origin. There is mounting evidence that these types of negative encounters engender clinical depression and anxiety and contribute to hypertension and other medical sequela. If a patient self-defines as having an emergency by showing up at the emergency department, the problems that cause that person to come deserve our respect.

A study of racial and ethnic patterns of emergency department use found that four times as many African Americans and Hispanics as whites report the emergency department as a source of care.79 Patients who “overuse or abuse” the emergency department are seen as “bad patients,” but the reasons given in this study for patients’ use of the emergency department are entirely rational: (1) Individuals seen in the emergency department need not request an appointment to receive care; (2) emergency departments provide sophisticated medical technology; (3) emergency departments operate 24 hours a day; (4) emergency department services are often covered by health insurance and other options are not; (5) emergency departments have a tradition of free care; (6) many communities lack culturally competent private practitioners; and (7) emergency departments are often close to inner-city neighborhoods, whereas many primary care providers have abandoned the city center environs for the suburbs. These reasons may explain, at least in part, why U.S. emergency departments had an estimated 115.3 million visits in 2005.

To practice good medicine in this health care and social environment, emergency physicians must critically question and reframe the moralistic good patient/bad patient paradigm. We, like our patients, are at the whim of forces beyond our control, and both patients and practitioners will experience higher levels of satisfaction if these issues are addressed directly. Patients must take responsibility for their own behaviors whenever possible, but physicians can and should work with health care institutions to adopt policies that improve access to culturally competent health care. These actions can help create a safe environment for both practitioners and patients.

**RECOMMENDATIONS**

Diversity among the emergency department patient population poses a challenge to emergency physicians. Recognition of cultural differences, knowledge about diverse cultures, awareness of the health impact of cultural beliefs and practices, and sensitivity to patients’ needs can reduce access barriers and improve clinical outcomes and hospital-community relationships, while reducing the number of repeat visits and the cost of health care. Diversity education also creates a rich environment for conceptualizing and researching health problems.80,81

There are many opportunities for emergency departments and there are many opportunities for their institutions to improve their care of multicultural communities. These include plans to address problems related to (1) a lack of protocols for patient care; (2) a lack of resources for translation and cross-cultural interpretation; (3) an incorrect perception that attention to cultural competence adversely affects flow and efficiency; (4) a lack of cross-cultural teaching guidelines and standards in medical education; (5) inadequate recruitment and retention of minority residents, faculty, and practitioners; and (6) a lack of pathways for communication and collaborative work with communities.

Concrete recommendations, based on the CLAS standards, have been proposed for pediatric emergency settings and can be applied universally: (1) Institutions should employ trained medical interpreters and a diverse workforce; (2) pharmacies should label prescriptions and provide medical instructions in the patient’s primary language; (3) administrators should post multilingual signs and ensure that handouts and forms are translated; (4) quality improvement programs should collect and analyze data and provide information to monitor

---

**BOX 198-1 BASIC SKILLS IN AN INTERCULTURAL CURRICULUM**

- Communicate an interest in and respect for the patient’s culture.
- Tactfully and respectfully ask for general cultural information (e.g., herbal remedies, acupuncture, coining, moxibustion, or other cures attempted).
- Elicit the patient’s understanding of and beliefs about illness or health problems.
- Request information regarding folk medicine beliefs—for instance, “mal ojo” (the evil eye or evil spirit) among Mexican Americans, voodoo among Haitians, yin and yang among Chinese patients, “rootwork” among African Americans, and “spiritism” (the ability of spirits to make people sick or cure them) among Puerto Ricans.
- Interpret verbal and nonverbal behaviors in a culturally relevant manner.
- Negotiate a culturally appropriate health care plan with the patient and his or her family as partners.
- Demonstrate an ability to work as a team with a medical interpreter in the bilingual medical encounter.

---

**BOX 198-2 POLICIES FOR INSTITUTIONAL IMPROVEMENT**

Educate emergency department personnel about the circumstances of patients’ lives and the interesting cultures that have evolved to deal with these circumstances using a variety of formats:

1. A series of hospital inservices to provide information about each specific patient group that uses the institution.
2. Small focus groups with patients to improve our understanding of our patients’ needs and begin the process of freeing providers from racial and ethnic stereotypes that create barriers to good medical care.
3. Training utilizing videotapes and role-playing exercises to enhance movement along the cultural competence continuum.
4. Meet with community organizations to build trust and create partnerships for preventive education.
5. Hire employees who reflect the culture, ethnicity, and socioeconomic background of emergency department patients to improve the quality of services.
6. Provide interpreter services, visual aids, and other educational materials in a variety of languages, and provide multilingual health education classes.
7. Participate as an institution in community health fairs.
outcomes based on race/ethnicity; and (5) a diverse group of patients should be enrolled in research studies to improve outcomes.82

Recommendations from the IOM report for a series of additional legal, regulatory, and policy measures were highlighted in an Academic Emergency Medicine editorial and include the following: (1) patients in public managed care organizations should have the same patient bill of rights as patients in private health maintenance organizations, (2) the number of health care providers who are members of racial and ethnic minority groups should be increased, (3) resources must be adequate to enforce penalties for civil rights violations, (4) incentives to promote disparities should be stringently limited, (5) health care professionals should have opportunities for cross-cultural education, (6) patient participation in decision-making should be enhanced through education, (7) community health care workers/advocates should assist patients to negotiate the health care system successfully, (8) the diversity of faculty and residents must be improved, (9) a cross-cultural curriculum should be developed for residency training and continuing education, and (10) physicians must educate themselves and the general public about the need to eliminate racial and ethnic disparities in health care.83

### SUMMARY

Changing demographics manifest themselves in a diverse emergency department patient population, and emergency department practitioners must learn to be culturally competent and promote systemic change to provide quality care. Essential cultural competence tools for providers include recognition of cultural differences, respect for individual opinions and perspectives about health and illness, and, most important, the ability and willingness to negotiate differences to offer the best opportunity for good health care outcomes. Culturally appropriate health care systems must be incorporated into emergency departments, which serve as the gateway to our health care institutions.

Basic skills proposed in an intercultural curriculum developed by Goldstein and associates for internal medicine residents can apply equally to emergency physicians (Box 198-1).84 Policies that will promote cultural competence, increase patient satisfaction, and improve health outcomes include those listed in Box 198-2.

CHAPTER 199  Process Improvement and Patient Safety
Shawna J. Perry, Robert L. Wears, Pat Croskerry, and Marc J. Shapiro

PERSPECTIVE

The overall process of patient care in the emergency department (ED) begins with the initial decision by the patient (or caregiver or family) to seek emergency assistance and ends with the patient’s disposition and follow-up. The care process is highly complex, with many separate components, people, and interfaces with other processes in the health care organization (Fig. 199-1). This complexity, among other things, provides many opportunities for process failures, “errors,” and adverse outcomes. Although process failures in health care have been studied for decades, most of that effort originated from outside of the field of health care, with health care professionals largely unaware of it.1

This began to change in the early 1990s when the Harvard Medical Practice Study reported that almost 4% of hospitalized patients suffered significant adverse events during their care and that almost 30% of these were due to human “error.”2 The study noted that failures in ED care accounted for only approximately 3% of all adverse events, but it estimated that more than 90% of adverse ED events were judged to be preventable. This study and others ultimately led the Institute of Medicine (IOM) to issue a report in 1999 titled To Err Is Human: Building a Safer Health System.3 This report provoked the interest of the media and the general public and thrust the issue of safety in health care onto the national agenda. The major accomplishment of the IOM report was the introduction of some of the fundamental concepts regarding safety in complex systems for the first time into the world of health care. The most transforming concept was the idea that failures (or “errors”) in care were not the result of bad decisions or bad individuals but were instead intrinsic properties of the processes of care in the health care system. Thus, efforts to reduce these failures should be focused on changing the processes of care rather than identifying, retraining, or punishing the workers.

The response within health care was mixed. Most health care professionals focused on the projected number of deaths due to “error,” arguing that they were either too high4,5 or too low,6 and a third, smaller group argued that the concept of “error” was essentially contestable and thus an approach aimed at counting “errors” was fundamentally flawed.7 The transforming concept of “system failure” rather than “human error” gradually gained acceptance, despite going against the natural human tendency to believe that individuals cause outcomes. This viewpoint is problematic because it undermines a clinician’s sense of free agency; health care providers prefer not to view themselves as trapped in a system that is moving inexorably toward a bad outcome.

Within emergency medicine, safety and quality have been addressed by task forces, interest groups, and special sections examining the practice of emergency care, its processes, and environments using tools from the “science of safety”8 to improve performance and cultivate patient safety. A basic curriculum for teaching about safety at the undergraduate level was developed with similar efforts taking place to implement safety concepts into medical education.9

Interesting lines of research on the safety and processes within emergency care have been performed, with a number of patient safety case reports published in the emergency medicine literature.10 Chisholm and colleagues11 reported that emergency physicians are interrupted, on average, approximately once every 6 minutes and that two thirds of those interruptions cause a change in task; this is important because both interruptions and task switching frequently lead to process failures. Fordyce and associates12 reported that self-detected errors occurred in almost 20% of all ED cases but that only 2% were associated with adverse events. Fordyce and associates’ work emphasizes that errors are ubiquitous but only rarely combine with other factors to produce adverse events, and it supports the notion that focusing on eliminating errors is not likely to be a productive strategy for improvement.

Coiera and colleagues13 studied emergency physicians in Australia and reported high communication loads and found similar levels of interruptions. Morey and coworkers14 reported that specific training of emergency physicians and nurses to work together in teams led to reductions in failures and improved performance. Perry and colleagues15,16 identified significant delays related to ED layout, with time to assessment of chest pain patients being greater for patients placed behind a door or who were 25 feet or farther away from the physicians assigned to care. These examples of safety research in emergency care demonstrate the wide range of known and unknown contributors to patient safety and the importance of the work processes that overlay this very complex work environment.
Many characteristics of emergency medical practice make it vulnerable to failures (Table 199-1). This section focuses on some of the principal factors that contribute to adverse outcomes and how they might be better managed to improve safety.

**Emergency Department Design/Human Factors and Ergonomics**

Two frequently overlooked contributors to lowered safety in any work environment are the design of the workspace and the engineering of the tools, technology, and procedures used to do the work. This is especially true for EDs because the majority were not designed for the care actually being delivered there. Emergency department caregivers are required to adapt to the space by creating “work-arounds” to cope with the limitations and impediments of the workspace.

Consistency is rarely found in equipment across or between areas. For instance, the blood pressure monitor in the ED is often not the same type or model as that used in the radiology department when the patient goes for diagnostic tests. In addition, tools and technology are seldom developed or assessed for their “user-centered design” or ability to be integrated into existing workspace and the associated hazards for doing so. This is most apparent with regard to health information technology, which is often introduced for improving safety and quality; however, embedded latent features that can produce clinical failures that are “hard to see” have been demonstrated. Study of computerized physician order entry by Koppel and colleagues showed that the software facilitated 22 types of medication error risks; for example, displays that prevented a coherent view of the patients’ medications; for example, displays that distorted the mind’s trajectory.) Sources of failure may occur in parallel or at multiple stages in the sequence and are often additive in their overall effect on patient safety.

**Sources of Failure in Emergency Care**

The practice of emergency medicine is integral to the health care system in the United States and has unique characteristics that influence safety and the delivery of care. Understanding and managing the factors that contribute to patient safety is critical to the success of emergency care. This section identifies some of the principal factors that contribute to adverse outcomes in emergency care.

*Intrinsic factors are intimately part of the nature of emergency care and as such are not amenable to change but instead must be compensated for.

Extrinsic factors are in principle manageable and typically relate to resource constraints.

Low signal-to-noise ratio refers to the low likelihood of a critical diagnosis compared with a benign diagnosis for similarly presenting symptoms and findings (e.g., subarachnoid hemorrhage vs. tension headache).

Surge phenomena refers to the rapid changes in volume and acuity, routinely experienced in many emergency departments.

The contribution of poor design to the difficulty in maintaining safety in a health care environment is generally overlooked by staff, who cope with these difficulties as “part of the job.” Vigilance is the common solution but despite caregivers’ best efforts cannot be sustained given competing demands for their attention. This increases the risk of a failure not being...
recognized as linked to the workplace, the procedures, or the equipment, despite being “tightly coupled” to any or all of these.

Overcrowding

Emergency department overcrowding has long been recognized as a major source of time-delay failures and a threat to patient safety. It is important to understand that such delays are not simply an inconvenience to the patient but may give rise to significant adverse events. For example, patients with atypical presentations of severe illness who have been mis-triaged to low levels of acuity may experience inordinate and, occasionally, fatal delays. In other cases, such as community-acquired pneumonia, cellulitis, lacerations, and others, more expedient care may significantly improve the course of the illness. A significant proportion of patients who leave without being seen may have serious illness and incur delays in diagnosis and treatment. At the other end of the process, when the patient is ready for admission to the hospital from the ED, further time-delay errors may occur (see Fig. 199-1). Not only do such delays create throughput problems for the ED and contribute to overcrowding by front-end loading or “entry block” but also they give rise to discontinuities in care and may lead to adverse events that are difficult to identify because they manifest once the patient has left the ED.

Information Gaps

Missing information is common in emergency care and can significantly affect quality of care. Hospital records, especially discharge summaries, details of past medical history, and other important information is often difficult to access in an expedient manner, even with electronic medical records. Referral notes sent in by family doctors with the patient may not reach the emergency physician or may not contain relevant or significant details. In these situations, emergency physicians make clinical decisions and take action on the basis of incomplete, limited, or erroneous information. Emergency clinicians often end up not seeking additional or clarifying information due to time pressures, patient volume, or limited methods for obtaining more information (e.g., referring physician’s office is closed), essentially accommodating to this “gap” in continuity of care and the associated increase in patient risk.

Performance-Shaping Factors

Blaming individuals for “errors” in the ED contributes little to an understanding of risk, vulnerability, and failure. A wide variety of ambient, systemic conditions in the ED contribute to the majority of adverse events and near misses that occur (see Table 199-1). Some performance-shaping factors can be considered to be “intrinsic,” part and parcel of the milieu of emergency medicine and thus not amenable to direct control (e.g., cognitive workload, multiple distractions and interruptions, and high acuity). These factors must be managed by strategies for buffering or mitigating their effects. In contrast, other “extrinsic” performance-shaping factors typically reflect limitations of resources (e.g., staffing ratios, production pressure, and ED layout). When resources are limited, a tradeoff can occur in the ability of the ED to provide safety and quality in patient care. This condition is referred to as RACQITO (resource availability continuous quality improvement tradeoff), a concept derived from speed-accuracy tradeoffs in industrial settings.

Violation-Producing Factors

Although at first one might think that violations of organizational policies, rules, and procedures would always be culpable causes of failures and adverse events, the modern approach to safety has pointed out that some violations are actually necessary for the safe functioning of the system, and others fall somewhere in between. Aside from recklessness, drug use on the job, moral failings, and other egregious acts, research in other domains has identified other factors that are associated with the occurrence of rule and safety violations (Box 199-1). The “normalization of deviance” is an accumulated tolerance of small variances from safe operating conditions that develops over time, ultimately compromising safety. This is evidenced in overtaxed EDs coping with overcrowding of patients (e.g., performing evaluation and management of patients in hallways). Violations can also occur in response to perceptions of authority. They may occur through a directive supporting violation from an authority figure (e.g., nursing supervisors order admitted patients moved to inpatient beds without calling to report if there are delays in reaching inpatient nurses), the absence of a disapproving authority (e.g., physicians leaving shifts early and the medical director does not address the behavior), or from an individual’s self-perception that he or she is authorized to disregard or deviate from prescribed procedures (e.g., ED electrocardiograms done on patients in chairs because there are no available stretchers).

Fluctuations in mood can also contribute to violations for a variety of reasons and will result in inconsistent clinical performance; males are more likely to break safety rules and engage in more risk-taking behavior than females. Risk-seeking and risk-averse attitudes have been associated aspects of decision-making in the ED.

Teamwork

Good teamwork is essential to the safe practice of emergency medicine, but emergency caregivers are not trained or evaluated as teams. Teamwork training in other fields, such as aviation, has been successful in reducing failures related to poor communication, cross-monitoring (observing others’ behaviors to reduce risk of failure and share workload), and authority
gradients (both within and between professions).\textsuperscript{45} Work on transferring teamwork training principles to emergency medicine suggested that teamwork failures were involved in approximately 40\% of malpractice cases.\textsuperscript{46} The lack of cross-monitoring across team members and the failure of advocacy or assertion on behalf of the patient by caregivers to avoid patient harm were two of the most frequent factors identified. A multidisciplinary teamwork training course implemented in nine EDs showed a significant improvement in quality of team behaviors and a sixfold decrease in observed clinical errors.\textsuperscript{14} Teamwork is not a specific fix for any one type of error, but it should be viewed as one type of adaptable human factor intervention with a set of teachable skills and behaviors capable of increasing system resilience and safety, which are hallmarks of high-reliability organizations.\textsuperscript{47}

Teamwork training requires a change of culture, which can be difficult for ED staff. Institutional and ED leadership must be fully committed to the process before implementing teamwork training for all staff. Resistance to behavioral change is likely to be encountered, and it will be necessary to demonstrate the clinical relevance of this training. High-fidelity medical simulation supported by audiovisual feedback offers the educational methodology to help clinicians and staff understand the necessity of behavioral change.\textsuperscript{48} A major unanswered question is how to embed teamwork behaviors into medical training and how to sustain the behaviors over time.

**Authority Gradients**

Almost all human groups have some form of authority gradient among members. This hierarchy can be based on profession (e.g., doctors have greater authority than nurses) or organizational rank (e.g., attending physicians have more authority than residents). Ideally, information between team members should flow freely, but this may not occur if low-authority members are inhibited by differences in seniority, stature, expertise, profession, or social status. There are clear examples of cases in which authority gradients have been responsible for adverse events.\textsuperscript{49} A work environment in which all team members feel comfortable expressing their viewpoint, especially if it is a dissenting one, requires cultural change that can begin with the physicians who occupy the highest authority position in the clinical setting. Authority figures have the ability to initiate change by recognizing the value of perspectives other than their own and eliciting them from other clinicians and staff (e.g., asking a patient’s nurse what he or she thinks may be going on with the patient). Senior clinicians are in a powerful position to bridge gradients by fostering open communication through multidisciplinary rounds, demonstrating that they are approachable (e.g., acknowledging staff by name), and the use of clinical narratives from their own experience that illustrate near misses and judgment failures.\textsuperscript{50}

**Cognitive Properties of the Mind**

The human mind has characteristic dispositions to respond to particular stimuli and contexts in specific ways. A great deal of effort has gone into identifying and describing these; more than 30 cognitive dispositions to respond have been described.\textsuperscript{17,51,52} A number of strategies have been proposed to reduce the adverse outcomes associated with cognitive dispositions to respond.\textsuperscript{53}

The overall process of patient care in the ED is driven by a process of making clinical sense out of multiple sets of fragmented, tangential, and interrupted stimuli. This is aimed at making an accurate diagnosis if possible or, more commonly, a useful framing of the problem, which can determine management and disposition. Although many diagnoses, such as lacerations, dislocations, fractures, and foreign bodies, are self-evident, others (e.g., chest pain, fever, headache, abdominal pain, and syncope) are often associated with high levels of diagnostic uncertainty and are more likely to lead to problems. Cognitive biases can frequently be identified in retrospect following diagnostic failures,\textsuperscript{54} but the problem of hindsight bias makes this identification problematic.\textsuperscript{55}

In addition to cognitive mental properties, the emotional state of the physician can affect his or her decision-making; this has been referred to as visceral bias.\textsuperscript{15,52} Relatively little attention has been directed at the important role of affective bias in decision-making. Although processes such as countertransference, fundamental attribution error,\textsuperscript{41} and the economy of perception that underlies stereotyping are well understood in psychology, health care workers are typically less aware of them (e.g., “She’s a drug seeker,” “He’s a frequent flyer,” and “She just wants attention”) and their effect on clinical interactions.

**Fatigue and Shift Work**

Both fatigue and shift work contribute to performance failures,\textsuperscript{56} but relatively little research has been directed at their respective impacts on clinical performance in the unique milieu of the ED.\textsuperscript{37} Although the two are often considered together, they are different entities and exert both qualitatively and quantitatively different effects on performance.\textsuperscript{58} Fatigue has a number of determinants separate from those associated with shift work (Fig. 199-2).

Shift work has extensive, well-documented, detrimental effects on health that, in turn, have an impact on well-being and job performance.\textsuperscript{59} Importantly, it leads to disruption of circadian rhythms that inevitably result in sleep deprivation. Circadian dysynchrony largely occurs through missing sleep in the anchor period, approximately midway through the sleep phase when core temperature and arousal level are at their lowest. It has been stated that the performance degradation of someone who has been up all night is roughly equal to that of a person with a blood alcohol level of 0.1\% (Box 199-2).\textsuperscript{60}

---

**Figure 199-2.** Relationships between shift work, fatigue, and performance.
The acute effects of sleep deprivation are well-known, but the chronic effects are less appreciated. Invariably, working a night shift results in less sleep the following day, and subsequent sleep is often disrupted and fragmented in the struggle to restore the circadian rhythm before the night-shift cycle repeats itself. This results in the accumulation of a sleep debt that has a significant impact on performance. A study of anesthesia residents on a normal work schedule, with no on-call duty in the preceding 48 hours, showed daytime sleepiness scores comparable to those of patients with narcolepsy or sleep apnea.61 The on-call schedule of these subjects (five periods per month) entailed considerably less sleep deprivation and fragmentation than an average emergency physician's schedule. Increasing age is associated with decreased tolerance for sleep deprivation.62

Performance declines as work hours increase,63 but the optimal shift length in the emergency department is unknown and difficult to delineate for several reasons. The relationship with workload or acuity is not well appreciated, and some workers exhibit contradictory incentives, such as preferring to work longer shifts to get more days off. More recovery time between shifts might be expected to enhance job performance, but these issues remain relatively unexplored. A survey of emergency physicians found a preference for 8-hour over 12-hour shifts,64 but it is not known whether job satisfaction in the ED translates into improved clinical performance and fewer adverse events. Other ambient conditions within the ED, competing commitments outside the ED, age, ill health, and other factors all contribute to fatigue, with evidence pointing toward additional health implications for emergency physicians.65

The appropriate management of shift work and fatigue to improve patient safety is not well understood, and further research is needed in this area. In most high-hazard industries, the assumption is that fatigue and long, aberrant work hours lead to poor performance; however, in the health care industry, concerns regarding discontinuity of care and difficulties in changing medical culture have obscured these issues. Given that medical personnel, like all human beings, function sub-optimally when fatigued, efforts to reduce fatigue and sleepiness should be undertaken, and the burden of proof should be in the hands of the advocates of the current system to demonstrate that it is safe.66 In the meantime, shift scheduling should be optimized to reduce the impact of circadian disruption, and ED personnel should practice good sleep hygiene. Some basic approaches have been reviewed (Box 199-3).67,68

PROBLEM AREAS IN EMERGENCY CARE

The mechanisms of failure within the ED are remarkably variable, with a cadre of known and unknown contributors. Areas of consistent concern within emergency medicine include triage, technical procedures, laboratory and radiographic tests, transitions in patient care, orphaned patients, and medications.

Triage

The point of entry of all patients into the ED is through triage. Triage, or sorting by acuity, is by definition an abbreviated decision-making process that can never be completely safe because of the limited information available, lack of time invested, and the variety of presentations of illness and injury. An additional problem is that there is a low “signal-to-noise” ratio, leading to inaccurate assessments and inappropriate patient management. A study of 500 general internists in an urban medical center found that only 20% of the 6000 patients seen each month were correctly triaged.69 The appropriate management of shift work and fatigue to improve patient safety is not well understood, and further research is needed in this area. In most high-hazard industries, the assumption is that fatigue and long, aberrant work hours lead to poor performance; however, in the health care industry, concerns regarding discontinuity of care and difficulties in changing medical culture have obscured these issues. PROBLEM AREAS IN EMERGENCY CARE

The mechanisms of failure within the ED are remarkably variable, with a cadre of known and unknown contributors. Areas of consistent concern within emergency medicine include triage, technical procedures, laboratory and radiographic tests, transitions in patient care, orphaned patients, and medications.

Triage

The point of entry of all patients into the ED is through triage. Triage, or sorting by acuity, is by definition an abbreviated decision-making process that can never be completely safe because of the limited information available, lack of time invested, and the variety of presentations of illness and injury. An additional problem is that there is a low “signal-to-noise” ratio, leading to inaccurate assessments and inappropriate patient management. A study of 500 general internists in an urban medical center found that only 20% of the 6000 patients seen each month were correctly triaged.69
ratio for a number of serious conditions (i.e., when the incidence of a serious condition is far exceeded by that for a benign condition, but their clinical presentations are similar). Inevitably, the triage process involves tradeoffs between sensitivity and specificity. Undertriage for a particular patient would have a greater potential for an adverse event than overtriage, whereas overtriage affects resource utilization and may have an impact on the care of other patients.

Triage assessments are important contributors to process failures and adverse events. Beyond treatment delays, which may occur with undertriage or be produced by overtriage, an incorrect assessment may be the triggering event that initiates a chain of failures. Geography can become destiny, and an inappropriate triage to a specific treatment area may create a bias in the minds of the treating clinicians and staff. The use of five-level triage systems for adults and children, with excellent inter-rater reliability, offers an opportunity to reduce the risk associated with undertriaging.69,68

### Technical Procedures

The practice of emergency medicine requires proficiency in a wide range of procedures with varying degrees of difficulty. Patients who require procedures are at greater risk for adverse events.15 Contributing to this higher risk include not only problems with proficiency but also a low frequency for use of higher risk procedures. Critical procedures, such as cricothyrotomy, pericardiocentesis, and endotracheal intubation, are rarely performed in many EDs. When they are needed, they are highly consequential events under significant time pressure for intervention, therein reducing opportunity for refreshing skills prior to performing the procedure. The acquisition and especially the maintenance of a requisite level of skill is an important problem in emergency medicine. Simulation techniques have considerable potential here,69 but require both capital and human investment to be effective.

### Laboratory

The interface between the ED and its ancillary services is critically important. Failures can occur at three phases of laboratory processes. Preanalytic errors mostly occur through inappropriate collection of specimens due to lapses in technique, timing, and identification of both patient and specimen. Analytic errors refer to those that arise directly from the testing process. Postanalytic errors occur after the test result has been obtained and can take many forms (e.g., keyboard entry errors, overlooked or lost data, and failure of results to reach physician). Studies on a blood bank and a stat lab both found that the majority of failures occurred in the pre- and postanalytic stages, with less than 5% in the analytic stage.20,21 Overall, the laboratory defect rate is less than 1%, but the number of exposures is very large. Of the failures that do occur, up to 50% may have a moderate impact, with up to 8% having a severe impact on patient care.72

### Radiology

Radiographic imaging is a critical aspect of diagnosis and management in the ED. Although patient identification and wrong-side problems are important sources of failure, the majority lie in interpretation. Assuming the radiologist’s interpretation to be the criterion standard, the rate of errors in interpretation by emergency physicians and residents may be as high as 16% for plain radiographs and more than double that rate for computed tomography scans.23 Clearly, not all misinterpretations are consequential, and emergency physicians typically seek the advice of the radiologist when they recognize difficult interpretations. The introduction of digital imaging and picture archiving communications systems has resulted in new patient safety issues related to usability, the effect of monitor resolution on interpretation, and reconciliation of ED physician and radiology readings.74 Significant interpretation errors can be detected with prompt review of all films by the emergency physician and radiologist, but effective procedures are required to ensure that timely and appropriate feedback and review occurs. This approach has been demonstrated to substantially reduce the rate of clinically important misinterpretations.75

### Transitions in Patient Care

The need for 24-hour access to care and the fragmented nature of health care delivery require the occurrence of transitions of care between providers, either within the ED (at shift changes) or between the ED and other care areas (when patients are admitted, transferred, or discharged). The shift “sign-over” or “handoff” is generally thought of as a communication activity performed for the transfer of clinical information, but it also embodies the transfer of responsibility and authority from one provider to another. The sign-over also conveys general situational awareness (e.g., the state of the department, hospital, and city) and provides a forum for reviewing decision-making and treatment plans.

There has been little study of these transitions of care, despite their ubiquity and importance to the specialty.20,76 Sign-overs are highly variable in their content, the number of individuals involved, the physical configuration (e.g., walking, stationary, and at bedside), the tools used to facilitate the transition (e.g., white boards, medical records, and written notes), and the length of the transition process. Although widely regarded as providing a major contribution to adverse events, sign-overs also provide an opportunity for review of decision-making by clinicians and may provide opportunities for recovery by bringing “fresh eyes” to a patient’s case.20,76

Potential threats to high-quality transitions include the following:

- Interruptions during the turnover (e.g., phone calls and sidebar conversations) can cause a loss of focus and lead to the omission of important information.
- Lack of consistent structure to the turnover: Although the traditional case presentation narrative is generally followed (chief complaint, history, physical examination, initial laboratory results, impression, and plan), the case presentation format does not automatically remind participants of pending or as yet uncompleted tasks.
- Patients are commonly “marked” in ways that can sometimes be helpful but sometimes harmful, especially for at-risk groups such as the homeless, psychiatric patients, alcoholics, or drug abusers.

Common sense and well-meaning approaches such as standardizing verbal content and compulsory use of sign-over checklists risk extinguishing latent safety features inherent to them without further research of this complex and vital work tool for emergency medicine and health care overall.

### Orphaned Patients

Orphaned patients are those who have suffered temporary loss or diminished supervision or accountability for their ED care. This may occur at several stages in the process. Patients who are seen and assessed at triage and then wait in the waiting
area are temporarily orphaned. Those who are brought in by paramedics sometimes remain on stretchers for hours before being admitted to the ED. Patients who leave without being seen or before treatment is completed have “orphaned” themselves. Patients can also be temporarily orphaned out of the ED for radiographic studies or other special tests. Occasionally, patients get “lost in the shuffle” and are overlooked at shift change, or they may get “lost” after one or more consultations with other services. With prolonged wait times, occult conditions can mature to serious and potentially catastrophic levels. A significant cause of orphaning in some EDs is the “boarding” of admitted patients because no inpatient beds are available. In such cases, patients may be put in holding areas in or adjacent to the ED and receive sporadic care from a succession of caregivers who know increasingly less about their conditions. The risk of harm to patients caught in this “gap” within the ED is not well studied.

**Medications**

Medication errors constitute the largest proportion of failures in most general studies, with failures occurring in all six steps of the process (prescription, transcription, dispensing, administration, monitoring, and discharge).78 Many EDs take on the dispensing role, obviating input from the pharmacy, where many errors are corrected. In addition, team communication errors can contribute to many failures: missed medications, wrong medications, and duplicate dosing. Pediatric patients are at higher risk; drug errors are no more common than in adults, but they are typically more serious.79,80

The presence of a pharmacist on the clinical team has been shown to reduce medication errors in several settings.81 There is great interest in the potential for computer technologies, such as bar coding or computerized physician order entry, to enhance medication safety. However, despite some successful demonstrations, widespread implementation has not occurred, and there is evidence that such systems introduce new problems to replace old ones.82 The Institute for Safe Medication Practices has recommended certain problematic practices be avoided in writing orders or prescriptions.83 Success in this area will require more than just individual attentiveness; nurses, unit secretaries, and pharmacists will have to feel comfortable challenging improper usage by physicians.

**CONCLUSION**

The safe management of patients in the ED depends on a multiplicity of processes. All appear vulnerable to failure, yet all have the potential for improvement through judicious process management. Efforts by front-line workers will not be sufficient, and so considerable effort will be required at the administrative or “blunt end” of the system.84

Safety in complex dynamic environments, such as the ED, is itself dynamic. Safety is a “nonevent” because it is evidenced by the absence of things that should not or do not occur, such as administering a medication to the wrong patient. It cannot be banked for future use but is created by workers in a well-designed and supportive organizational environment. Achieving safe performance in settings such as the ED is analogous to fighting a guerilla war: There are no dramatic victories, but there are occasional horrific defeats, with no end in sight. The establishment and maintenance of successful safety cultures within health care will require constancy of purpose by health care organizations, a willingness to adopt new ideas and tools from outside of health care, and commitment to continued effort and investment.

Definitions

Ethics is the application of values and moral rules to human activities. Bioethics, a subset of ethics, uses ethical principles to find reasoned and defensible solutions to actual or anticipated moral dilemmas facing clinicians. The moral precepts that underpin ethical decisions are derived from a variety of sources, including individual, cultural, and community value systems. Unlike the law, which is relatively rigid and, particularly in the case of scientific and medical issues, can lag years or even decades behind modern developments, the bioethical construct allows a greater flexibility in decision-making. This is a crucial factor in the emergency department (ED), which demands reasonable action. Emergency physicians (EPs) often are called on to identify a patient’s personal, cultural, religious, or community values and to balance these values with their own personal and professional ethos. A working knowledge of bioethics greatly enhances the EP’s ability to make reasonable, ethical decisions in the limited time frame common to the practice of emergency medicine.¹

Unlike professional etiquette, which relates to standards governing the relationships and interactions between practitioners, bioethics deals with relationships between practitioners and patients, practitioners and society, and society and patients. Issues within the realm of professional etiquette include billing, referrals, advertising, competition, conflicts of interest, professional courtesy, employment and supervision of auxiliary personnel, the use of secret remedies and exclusive methods, and the location and appearance of an office, ED, or urgent care center. These are quite different from bioethics’ concerns of basic moral values and patient-centered issues. Although the two areas occasionally overlap, each relies on different standards, values, and problem-solving methods.

Ethics and Emergency Medicine

In the ED, the focus is inevitably on the inherent “medical” nature of each case; therefore, it should come as no surprise that ethical dilemmas often are not recognized as being in the ethical rather than the strictly medical realm. A second, related failing of the specialty is to misperceive ethics as embodying the “commands” of secular or religious law, or as a discipline that describes irresolvable issues.¹

This chapter addresses a number of ethical issues in emergency medicine. What follows are brief discussions of the relation of law to bioethics; bioethical values and principles; moral imperatives in emergency medicine; ethical oaths and codes; applying bioethics to clinical situations; bioethical dilemmas in emergency medicine; a rapid decision-making model for ethical dilemmas; advance directives; the relationship between consent, decision-making capacity, and surrogate decision makers; ethical issues in resuscitation; and ethical issues in public policy.
principles do not have universal support, just as the values implicit in many legal changes have divided U.S. society.

Rights and Duties

Significant overlap exists between legal and ethical decision-making. Frequently there is concurrence on basic issues. On occasion, clarity within the law can lead to clearer thinking in bioethics, and vice versa. Both law and bioethics, for example, use the term rights, as in “patients’ rights” and “the right to die.” This term, often used to advance an ethical argument about medical care, frequently is misunderstood or applied erroneously. A legal right is a demand that a person can make on another person, embodied in in personam rights, or against the state for recognition and enforcement of this demand, as in in rem rights. Most rights involved in bioethical discussions are in rem rights. These most often are negative rights because they entail someone else’s duty to refrain from doing something. A common source of ethical conflict is between “active rights,” the right to act or not act as one chooses, and “passive rights,” the right to not be acted upon by others in certain ways.5

Without a duty to act, there can be no rights. Both a moral and a logical connection exist between the rights and the duties of individuals; one cannot exist in the absence of the other. In general, a duty is an action required by the rights of others, the law, a higher authority, or one’s conscience.5 This obligation to act can be based on an individual’s personal values, professional position, or other commitments.5 For the physician, this duty to act is a role responsibility, at least specifically as a physician and possibly at all times. The role-duty link occurs “whenever a person occupies a distinctive place or office in a social organization, to which specific duties are attached to provide for the welfare of others or to advance in some specific way the aims or purposes of the organization.”4

In this circumstance, performance is not predicated on a guarantee of compensation but, rather, on a concern for another person’s welfare.5 The EP has just such a duty.

VALUES

Values are the standards by which human behavior is judged. Values are learned, usually at an early age, through indoctrination into the birth culture: from observing behavior and through secular (including professional) and religious education. Although many of these learned values overlap, each source often claims moral superiority over the others, whether the values are generic and cultural, legal norms, religious and philosophical traditions, or professional principles.6,7 Societal institutions incorporate and promulgate values, often attempting to solidify old values even in a changing society. In a pluralistic society, clinicians treat people with multiple and differing value systems, so they must be sensitive to alternative beliefs and traditions.

This section discusses the role of religious, patient, institutional, and professional values, including professional oaths and codes specific to emergency medicine.

Religious Values

Organized religions are recognized as keepers of society’s values. Even though various religions may appear dissimilar, most hold the golden rule, “Do unto others as you would have them do unto you,” as a basic tenet. Other moral rules that are common to most religions are listed in Box 200-1. Problems surface in trying to apply religion-based rules to specific bioethical situations. For example, although “Do not kill” generally is accepted, the activities that constitute killing, active or passive euthanasia, or merely reasonable medical care vary with the interpretation of the world’s religions as they do with the interpretations of various philosophers.8-10 As members of a democracy with significant populations practicing a number of religions, EPs should behave in a manner consistent with each patient’s values. The underlying question must be “What is the patient’s desired outcome for medical care?”

Not only religious but also family, cultural, and other values contribute to patients’ medical care decisions. Without asking, it is impossible to know what decision a specific person would make. An important point is that religion influences modern secular bioethics, which uses many religion-originated decision-making methods, arguments, and ideals. In addition, clinicians’ personal spirituality may allow them to relate better to patients and families in crisis.9

</tr>
</tbody>
</table>

The terms good and evil can be used to illustrate a stark dichotomy in ethical thought and values. The following is a current set of definitions that may help the physician find solutions to ethical problems. Good can be defined as what no rational person will avoid without a reason. Examples are freedom, pleasure, health, wealth, and knowledge. Evil can be defined as what all rational persons desire to avoid for themselves and for others they care about. Examples are untimely death, pain, disability, and loss of freedom or pleasure. Rational persons with deeply held religious beliefs may, for example, refuse blood transfusion, choosing a likelihood of death over the permanent pain and anguish they feel would ensue if they should violate their religious injunction.

Patient Values and Ethical Decisions

A key to making bedside ethical decisions is to know the patient’s values. Although many people cannot answer the question “What are your values?” physicians can get an operational answer by asking patients what they see as their goal of medical therapy and why they want specific interventions. The responses represent concrete expressions of patient values. In patients who are too young or are deemed incompetent to express their values, it may be necessary for physicians either to make general assumptions about what a normal person would want in a specific situation or to rely on surrogate decision-making. But with patients who are able to reason and communicate, care must be taken to discover what they hold as their own, uncoerced values.

Although each individual is entitled, and perhaps even required, to have a personal system of values, certain values have become generally accepted by the medical community, the courts, legislatures, and society at large. Autonomy and individual dignity, for example, are two such values: They have been considered fundamental and often are given overriding importance. Although some groups disagree about each of these values, this dissension has not affected their application to medical care.

</tbody>
</table>

**Beneficence**

At the patient’s bedside, beneficence (doing good) and confidentiality (holding information in confidence) have been long-held and nearly universal tenets of the medical profession. Similarly, personal integrity (the adherence to one’s own moral and professional standards) is basic to thinking and acting ethically.

**Justice**

The concept of comparative or distributive justice suggests that a society’s comparable individuals and groups should share similarly in the society’s benefits and burdens. Many society-wide decisions affecting thoughts and actions about the allocation of limited health care resources are based on this principle. Yet for individual clinicians to limit or terminate care on a case-by-case basis is an erroneous extrapolation of the perceived need to limit health care resource expenditures. Distributive justice is a policy concept, rather than a clinical model.

**Truth-Telling**

Personal integrity involves adhering to one’s own reasoned and defensible set of values and moral standards and is basic to ethical thought and action. Integrity includes a controversial value within the medical community—truth-telling. Some people feel that the patient has the right to know the truth, no matter what the circumstances, and have championed absolute honesty. Yet many of these same people, when patients themselves, have been appalled by their physician’s lack of sensitivity when relating unfavorable medical news. In this context, being honest does not mean being brutal; truth is best tempered with a modicum of compassion.

Physicians accept a lack of truth-telling, depending on the circumstances. When patient harm may result from failing to disclose the truth, such as happened in the infamous Tuskegee experiments on black men with syphilis, it is not only immoral but also probably illegal to withhold the information. Likewise, when failure to disclose information is strictly for the physician’s benefit, such as not telling a patient about a dismal prognosis or a medical error, the clinician’s behavior suggests serious ethical and legal deficits. Perhaps truth-telling is not universally accepted within the medical profession.

---

**FREQUENTLY CITED BIOETHICAL PRINCIPLES**

**Nonmaleficence and Autonomy**

The basic tenet all medical students are taught is nonmaleficence: “First, do no harm.” This credo, often stated in the Latin, primum non nocere, derives from the recognition that physicians can harm as well as help. With the physician’s fallibility recognized, patient autonomy is and has been for several decades the overriding professional and societal bioethical value. Autonomy recognizes an adult person’s right to accept or reject recommendations for medical care, even to the extent of refusing all care, if that person has appropriate decision-making capacity. It is the counterweight to the medical profession’s long-practiced paternalism (or parentalism), wherein the practitioner determines what is “good” for the patient, regardless of whether the patient agrees. Coupled with paternalism is coercion, the threat or use of violence to influence behavior or choice. The august figure in white combined with implied or explicit threats remains a potent force for counteracting patients’ wishes. The thrust of modern bioethics is to respect patients by honoring their autonomy (Box 200-2).
because of poor role models, lack of training in interpersonal interactions, and bad experiences, rather than because the value itself has been discounted. The issues become murkier when truth-telling, or lack thereof, involves a third party, such as a sex partner who has been exposed to an infectious disease.13

Confidentiality versus Privacy9

Stemming at least from the time of Hippocrates, confidentiality is the presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient’s permission.9 Health care workers have an obligation (duty) to maintain patient confidentiality. Occasionally, the law, especially public health statutes, may conflict with this principle, because they require physicians to report specific diseases, injuries and injury mechanisms, and deaths. Drug-seeker lists, long used in EDs, can be seen as violations of patient confidentiality, and especially without firm controls on patient entry and clinician access to these lists, they can directly harm patients.14 Rarely discussed are similar computer lists of previous ED visits that can be easily generated from most ED computer systems. The Health Insurance Portability and Accountability Act of 1996, a U.S. federal law designed to protect patient information, however, takes the principle of confidentiality to the extreme, resulting, paradoxically, in greater difficulty in obtaining crucial information needed to treat ED patients.

Privacy, which often is confused with confidentiality, is a patient’s right to sufficient physical and auditory isolation that they cannot be seen or heard by others during interactions with medical personnel.9 ED overcrowding, patient and staff safety issues, and ED design limit patient privacy in many cases.

The increasing use of telemedicine to render advice and guide procedures at remote sites also places a strain on both patient privacy and confidentiality. Suggested ethical guidelines for such practice can facilitate the use of these new technologies without sacrificing either patient rights or physician duties.15

Another recent development has been filming ED patients for public viewing. Such filming, whether for medical records, education, peer review, or “reality television,” encroaches on ED patients’ reasonable expectation of privacy and confidentiality, because the recording can easily be distributed or misused. Although good reasons exist to allow such filming with patient acquiescence,16 the standard is now to abstain from such filming for commercial purposes and to require patient or surrogate consent for educational purposes.17

■ MEDICAL AND MORAL IMPELMENTS IN EMERGENCY MEDICINE9

Professional Values

Emergency clinicians, in both the out-of-hospital care and ED environments, operate with four imperatives: to save lives when possible, to relieve pain and suffering, to comfort patients and families, and to protect staff and patients from injury. All but the last of these also are the imperatives of most other clinicians, although saving lives may occur more often and more dramatically in emergency medicine settings.

Clinical Competency

Although it is tempting to use the latest instruments or medications, physicians have a duty to obtain competency in new technologies, and to be informed of new medications, to decrease any risks to patients. Because there is little oversight of individual practitioners in this area, it remains a substantial matter for personal ethics.9

Emergency Medical Services Personnel Values

Emergency medical services (EMS) personnel are required to attempt resuscitation except when there is no chance that life exists (e.g., with decapitation, rigor mortis, charring of a body beyond recognition, decomposition). They usually have little leeway in whom to resuscitate, resulting in prolonged dying for some patients. The real answer is for primary physicians to educate the families of homebound, hospice-type patients to call their clinician to pronounce death, rather than 911.

Safety: A Unique Value

The last imperative, safety, is nearly unique to emergency medical clinicians. Both in the out-of-hospital and ED settings, clinicians often encounter dangerous situations in which the environment (e.g., fires, wilderness, floods), the patient, or a family member poses a threat. Although most try to accommodate basic patient rights, clinicians’ priority must be their own safety and the safety of their coworkers. This priority does not imply that clinicians should ignore patient safety, but only that they should first ensure their own safety if they or their colleagues are at risk.

■ CODIFYING PROFESSIONAL VALUES: ETHICAL OATHS AND CODES

Conflicting Principles

In the abstract, bioethical principles often appear simple. However, clinicians adhere not only to basic bioethical principles but also, at least tacitly, to a number of professional, religious, and social organizations’ ethical oaths, codes, and statements.9 This complexity can make for a confusing array of potentially conflicting bioethical imperatives. Because bioethical principles seem to be neither universal nor universally applied, the principles that are most patient-centered normally hold sway.

Organizational and Institutional Values

Institutions, including health care facilities and professional organizations, have their own value systems. Health care facilities, although relatively well standardized under the requirements of regulatory bodies and government agencies, often have specific value-related missions. Religiously oriented or affiliated institutions may be the most obvious of these, but charitable, for-profit, and academic institutions also have specific role-related values. The values of professional organizations often are set forth in their ethical codes.

Professional Codes

Through the years, the medical profession has codified its ethics more rigorously than any other professional group, incorporating many standard bioethics principles into its ethical codes and oaths. For generations, the existing part of the Hippocratic Oath set the ethical standard for the medical profession.10 Yet its precepts clash with modern bioethical thinking, and many subsequent professional codes have included what may best be termed economic guidelines and

professional etiquette, along with ethical precepts. EP professional values have been incorporated into organization codes, such as the American College of Emergency Physicians’ Code of Ethics, and into a more personal oath developed by the Society for Academic Emergency Medicine.

Most modern ethical codes prescribe only the same basic moral behavior for members to follow that is expected by the society at large and do not require any higher level of duty or commitment. In fact, many of the ethical issues that would seem to be important to medical specialties usually are not addressed in their codes. Even when topics of interprofessional interactions are excluded, existing medical professional codes differ markedly (Table 200-2). All, however, try to give a “bottom line”—that is, minimally acceptable—course of action.

### APPLYING BIOETHICS

#### Emergency Physician–Patient Relationship

The EP has a markedly different relationship with patients from that typical for other practitioners, especially those providing primary care (Table 200-3). EPs care for patients who are unfamiliar to them and to the institution. Practitioners who either know their patients or who care for them in less acute settings often have the time and the mechanisms for making sound ethical decisions, but EPs have more limited options. A suggested method for rapid, ethical decision-making in the ED setting is outlined in Box 200-3 and discussed in a later section.

### Recognizing Ethical Problems

Although physicians like to reduce all clinical situations to “medical problems,” today’s increasingly complex medical environment often produces problems that are inexorably intertwined with fundamental bioethical dilemmas. Some are obvious, but many are more difficult to recognize.

### Prioritizing Conflicting Principles

Once such dilemmas are recognized, applying bioethical principles to clinical situations can be confusing. When two or more seemingly equivalent principles or values seem to compel different actions, a bioethical dilemma exists. This situation is often described as being “damned if you do and damned if you don’t,” in which any potential action appears, on first reflection, to be an option between two seemingly equivalent goods or evils. In the following real case, taken from the book Ethics in Emergency Medicine, the attending physician can be said to be on the horns of a dilemma (involving two prickly but seemingly equal choices): Although only two options for

**A Rapid Approach to Ethical Problems in the ED**

Is this a type of ethical problem for which you have already worked out a rule, or is it at least similar enough that the rule could reasonably be extended to cover it?

- **YES**
  - Follow the rule.
- **NO**
  - Is there an option that will buy you time for deliberation without excessive risk to the patient?
    - **YES**
      - Take that option.
      - 1. Apply Impartiality Test.
      - 2. Apply Universalizability Test.
      - 3. Apply Interpersonal Justifiability Test.
    - **NO**

ED, emergency department.

Case Example: Conflicting Bioethical Principles

A 60-year-old man stabbed himself in the abdomen because of intractable pain from terminal pancreatic cancer, unrelieved by any medical therapy. A well-meaning friend, who happened to be in the house when the event occurred, called the paramedics, who brought him to the ED. Although the man will obviously bleed to death if not given aggressive care, neither the patient, who is still alert and oriented, nor his wife, who is present, wants any treatment other than pain control. A review of his chart confirms that his physicians are at a loss as to how to alleviate his pain and that he is expected to die within the next several weeks. The physician believes in respecting a patient’s autonomy, yet usually questions patients’ decision-making capacity when they attempt suicide. Such patients’ actions seem to raise the question of whether, in fact, they have a right or an ability to be autonomous. This physician also believes strongly in beneficence: helping those in need, relieving pain, and saving lives when possible. Beneficence suggests two alternative courses of action: palliative care or aggressive therapeutic intervention. Merely using analgesics and other comfort measures will abet a suicide; initiating aggressive medical and surgical interventions will prolong a dying process that the physician’s colleagues have found to be unresponsive to even palliative treatment. Which value takes precedence: patient autonomy or beneficence? And if beneficence predominates, should it be aimed toward relieving suffering, prolonging life, or a third option that could include both? Bioethics deals with problems that are neither black nor white—only gray.

**MEDICAL IMPERATIVES AND BIOETHICAL DILEMMAS**

Clinicians have their own ethical values, as do professional organizations and health care institutions. Conscience clauses permit clinicians to “opt out” when they feel that they have a moral conflict with professionally, institutionally, or legally required actions. These conflicts, which may have a religious, philosophical, or practical basis, pose a barrier to use of the normal ethical decision-making algorithm. When such conflicts exist, it is morally and legally acceptable, within certain constraints, for the physician to follow a course of action based on his or her own value system. The constraint generally requires that timely and adequate medical care be provided for the patient—which may be particularly difficult to achieve in emergency medicine. When conflicts over values exist, however, it is essential for the practitioner to recognize the patient’s identity, dignity, and autonomy, to avoid the error of blindly imposing personal values on another.

**Professional Value Conflicts**

The imperative to save lives causes the most conflict between EPs and intensive care unit (ICU) clinicians. EPs recognize that some of the intubations and resuscitations they perform will be unwanted by patients or surrogates. Nearly all EPs have on occasion been berated by an irate intensivist or private practitioner for resuscitating a patient “who should not have been resuscitated.” Many families have heard these physicians criticize the ED and ambulance staffs for overaggressive resuscitative efforts. Nevertheless, the lifesaving imperative begins when the ambulance is called.

One classic dilemma is that posed by the exsanguinating adult patient, awake and still with medical decision-making...
capacity, who explicitly states a refusal to accept any blood or blood products based on religious beliefs. The physician, with a professional duty and moral commitment to preserve life, does not agree with the patient’s decision. Yet society (through the benchmark of court decisions) has repeatedly sided with the patient. In this case the patient’s autonomy and right to practice his or her religion are recognized as the overriding values. The case becomes less clear when the patient does not have decision-making capacity, is a minor, or appears to be under external pressure to make a life-threatening decision.

Other examples of ethical problems and conflicts in emergency medical care are uncertainty regarding resuscitation efforts, especially when patients and families may not want such efforts; teaching, particularly in critical situations or using procedures performed on the newly deceased; EMS control, when administrative rules and good patient care conflict; helping others when one’s own life may be placed at risk; and patient access, such as limited financial and personnel resources in the face of obvious patient need. Even if these problems do not fit into the classic form of a dilemma, they may be recognized as bioethical problems because they require the clinician to make a choice between two (or more) accepted values.

Rapid Ethical Decision-Making Model

The rapid ethical decision-making method of ethical case analysis, described in Box 200–3, is designed as a way of avoiding an ethically incorrect course of action for the EP in need of a fast answer to an ethical dilemma. A decision based on a known precedent—the first step—is the most productive way to use this method. However, such decision making requires advance planning, in-depth reading, and thought regarding ethical problems. Just as with the indications for any emergency procedure, EPs should at the very least be prepared with a course of action for the most common ethical dilemmas they may face in the ED.

Even the prepared clinician, however, can encounter cases without relevant known precedents. With no precedent to rely on and no way to “buy time,” the practitioner must select a possible course of action and test it for ethical validity. In such instances, three tests—the Impartiality Test, the Universalizability Test, and the Interpersonal Justifiability Test—can be used. The Impartiality Test asks whether the practitioner would accept this action if he or she were in the patient’s place. In essence, this is a form of the golden rule. The Universalizability Test asks whether the practitioner would feel comfortable having all practitioners perform this action in all relevantly similar circumstances. This involves generalizing the action to all colleagues and then asking whether a rule for the contemplated behavior is reasonable. The Interpersonal Justifiability Test asks whether the practitioner can supply good reasons to others for the action. Will peers, superiors, or the public be satisfied with the answers? If the answer to the question posed in each of the three tests is affirmative, then the practitioner has identified a reasonable probability that the proposed action falls within the scope of ethically acceptable actions.

Advance Directives

The term advance directive describes several types of legal and quasilegal documents. These documents indicate what is to be done for a patient in extremis who is no longer able to give or withhold permission for medical treatment. Advance directives usually are written to avoid prolonging an inevitable, often painful or nonsentient dying process. However, they also can be used to instruct surrogates and the patient’s medical team to “do everything” whenever possible. Advance directives include the living will, durable power of attorney for health care (DPAH), prehospital advance directive (PHAD), and mental health advance directive (MHAD). Although do-not-attempt-resuscitation (DNAR), do-not-hospitalize, and out-of-hospital DNAR orders also are discussed in this section, they are not considered to be advance directives but rather are physician orders, because they are not patient- or surrogate-initiated. All play a role in emergency medicine.

Do-Not-Attempt-Resuscitation Orders

DNAR orders, also known as allow-natural-death (AND) and do-not-initiate-resuscitation (DNIR) orders (still somewhat naively called do-not-resuscitate [DNR] orders in many locales), are physician orders informing other medical personnel that they should not institute cardiopulmonary resuscitation (CPR) in the event of cardiopulmonary arrest. (The DNAR order is not strictly an advance directive but does serve to transmit a conditional order to other health care personnel and is operative only if the patient’s condition follows a certain pattern.) Ideally, this order is written only after consultation with the patient (who possesses decisional capacity) or with the patient’s family or surrogate decision maker. It usually is written only for patients whom CPR will not achieve the patient’s goals of therapy. These orders usually work well within a specific institution, but if patients are transferred to the ED from another facility, the act of transfer or the activation of the EMS system usually negates the order. This outcome can be directly contrary to a patient’s wishes regarding terminal care. However, if a patient arriving in the ED still has the capacity to make a decision concerning resuscitation, part of the EP’s duty is to document such a decision in the patient’s chart, including the specific actions to be limited, the circumstances of the discussion, and the people present during the discussion. Many institutions have now recognized that simple DNAR forms are inadequate descriptions for other health care personnel to interpret and thus have changed to or added a limitation-of-treatment form specifying exactly what is not to be done for a patient (e.g., antibiotics, blood products, mechanical ventilation, surgery).

Do-Not-Hospitalize Orders

One type of physician order that has been used successfully in many locales is the do-not-hospitalize order. Normally used for hospice and nursing home patients, it prevents many unwanted ED resuscitation attempts and procedure-laden hospitalizations. Do-not-hospitalize orders instruct nurses not to send the patient to the hospital if further medical interventions are not desired either by the patient or the surrogate decision maker. Compliance with this physician order allows people to die peacefully, rather than having the “last rights of CPR” performed when such interventions would be futile or unwanted. The only caveat to applying do-not-hospitalize orders is that staff members must understand that patients should still be sent to a hospital if they need palliative care not available in the nursing facility.

Out-of-Hospital Advance Directives

As of 2003, 43 U.S. jurisdictions had enacted methods whereby patients outside of health care facilities can avoid unwanted resuscitation attempts. These methods usually take the form of preparing either an out-of-hospital DNAR order or a prehospital advance directive (PHAD). Although often confused, the two forms differ greatly in their philosophies. The out-of-hospital DNAR order is a physician-originated document.
The PHAD is generated by a patient or legal surrogate, with little or no involvement by health care personnel. Both instruct EMS personnel who have been erroneously called at the time of death not to attempt to resuscitate the patient, or to stop resuscitation efforts if they have already begun when such a form is found. Both types of form have proved effective. The most common reason for having physician-initiated forms is the fear that murders and suicides could be aided by patient-initiated documents. In practice, this has not occurred.

Of the existing protocols, 34 were specifically authorized by statute, usually supplemented by regulation or guidelines. Eight states implemented protocol solely through regulations or guidelines, without a change in their legal code. Eight states have no statewide protocol in place. In an affront to patient autonomy, 39 are physician orders requiring a physician’s signature; 33 states require signatures of both a physician and the patient. Three protocols are patient-initiated advance directives that are valid with a witnessed patient signature, with no physician involvement required. These instruments are of variable complexity; some include liability protection for EMS personnel and base station providers, and some may be usable for pediatric patients. Table 200-4 contains a list of the elements ideally included in a PHAD/DNAR policy.

<table>
<thead>
<tr>
<th>Policy Scope</th>
</tr>
</thead>
<tbody>
<tr>
<td>To ensure maximum coherence and compliance, a comprehensive out-of-hospital DNAR policy should be endorsed by the widest possible jurisdiction, comprising local, regional, state, and the medical community, including the EMS governing body. Whenever feasible, legislative support for such a policy should be sought.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Policy Guidelines</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Note the established fact that current basic and advanced life support interventions may not be appropriate or beneficial in certain clinical settings.</td>
</tr>
<tr>
<td>• Develop a means to educate the public about the appropriate use of 911 after expected deaths.</td>
</tr>
<tr>
<td>• Establish the fact that comfort care and palliative care are affirmative actions for patients with DNAR orders. These appropriate interventions, including hospice and respite care, do not require EMS activation and often can be arranged by calling the patient’s physician in anticipation of death.</td>
</tr>
<tr>
<td>• Develop means to educate health care workers on topics of advance directives, including information on local out-of-hospital DNARs, community hospice alternatives, and bereavement services.</td>
</tr>
<tr>
<td>2. Establish consensus on the ideal identification device for DNAR directives to ensure continuity of care across settings.</td>
</tr>
<tr>
<td>3. Reiterate that initial resuscitative attempts usually are indicated when the patient’s wishes are not known.</td>
</tr>
<tr>
<td>4. Define the conditions under which an out-of-hospital DNAR order can be considered, including its use in long-term care settings and in the emergency department.</td>
</tr>
<tr>
<td>5. Define which patients have the decisional capacity to agree to a DNAR order and whether surrogates can sign such orders.</td>
</tr>
<tr>
<td>6. Establish a mechanism for determining the precedence of various directives, including living will, durable power of attorney for health care, and out-of-hospital advance directive (i.e., DNAR order).</td>
</tr>
<tr>
<td>7. Develop a statutorily prioritized list of surrogates to use when there are no advance directives and the patient’s decisional capacity is impaired.</td>
</tr>
<tr>
<td>8. Consider language acknowledging the growing home hospice movement as it concerns children, and incorporate provisions for document use in minors.</td>
</tr>
<tr>
<td>9. Establish that the decision not to attempt resuscitation must be an informed decision made by the patient or the surrogate.</td>
</tr>
<tr>
<td>10. Identify information that should be contained in the DNAR order and the authority that will be responsible for developing such a mechanism.</td>
</tr>
<tr>
<td>11. Identify the clinical procedures that are to be provided and those withheld in the adherence to the DNAR order, or specify the authority that will verify adherence.</td>
</tr>
<tr>
<td>12. Define the exact manner in which the DNAR order is to be followed, including the role of online medical direction. Each system should ensure that a communication path to access online medical direction is immediately available, when necessary.</td>
</tr>
<tr>
<td>14. Establish data collection and protocol evaluation to perform periodic operational assessments.</td>
</tr>
<tr>
<td>15. Identify permissible exceptions to compliance with DNAR out-of-hospital directives. For example:</td>
</tr>
<tr>
<td>• The patient is able to revoke a written directive at any time.</td>
</tr>
<tr>
<td>• The EMS personnel can cancel the out-of-hospital DNAR order if there are doubts about the document’s validity.</td>
</tr>
</tbody>
</table>

DNAR, do-not-attempt-resuscitation; EMS, emergency medical services.

Most living wills specify that the patient’s physician must have seen and accepted the document’s provisions in advance. This requirement establishes a physician who will act on the patient’s behalf. For physicians, it protects those whose value systems will not allow them to abide by the document’s provisions. It also encourages families and physicians to discuss the circumstances surrounding the time of death and the actions they can take. The EP will rarely, if ever, be in the position of having accepted a living will’s provisions. In the setting of an ED resuscitation, the best that a living will can do, assuming that the patient is correctly identified, is to suggest what the patient’s wishes were. It does not in any way restrict the EP’s actions.

The limitation of living wills is that they list specific actions—either to take or to eschew—in a particular set of circumstances. This specificity reduces the usefulness of such documents and has led to a more flexible and powerful advance directive that names a trusted surrogate decision maker, the DPAH.

**Durable Power of Attorney for Health Care**

A more commonly used advance directive that specifies a surrogate decision maker is the durable power of attorney for health care (DPAH). It goes by many other names, including durable power of attorney with medical provisions and medical directive. All states and the District of Columbia have statutes authorizing such directives. In its usual form, a durable power of attorney (other than for health care) takes effect immediately. However, a DPAH takes effect only when the individual no longer has the capacity to make his or her own medical decisions.

Typically, a relative or close friend is named as a surrogate, because such persons should know something about the patient’s values related to medical treatment. More than one surrogate may be named; they generally are listed in preferential order, with the first being someone who is able to be contacted and is willing and able to act as surrogate in making the decisions.

The DPAH allows more flexibility than a living will, because the surrogate is able to make any health care decisions that the patient would ordinarily make, including gathering new information and choosing among multiple treatment options as the medical situation changes. Optimally, the surrogate’s decisions are guided by written or oral directions the patient has left, including those in a living will. In reality, surrogates often consider many factors when making decisions.

**Mental Health Advance Directives**

Mental health advance directives (MHADs), also known as psychiatric advance directives (PADs), were introduced in the 1980s so that psychiatric patients could specify their preferences regarding future mental health treatment during acute psychiatric illnesses. MHADs allow psychiatric patients to document in advance their acceptance or refusal of particular types of mental health treatment and intervention. Some of these laws also incorporate authorization of proxy decision makers specifically for mental health treatment. Most MHADs can be revoked only if the patient regains decision-making capacity. In practice, civil commitment laws usually override MHADs, as do clinicians who, acting in good faith, consider the instructions to be inconsistent with accepted clinical standards of care.

**Nonstandard Advance Directives**

EPs occasionally encounter medallions, tattoos, or other indications that seem to be advance directives. To be useful, advance directives must be available to the treating clinicians when they are needed, be a product of the patient's (or sometimes the surrogate's) deliberations, and be understandable, and must be applicable in the patient’s current medical situation. Nonstandard directives, usually abbreviated or abstract (such as a tattooed symbol for “do not defibrillate”), fail to meet these requirements. Of special concern is whether the patient or the surrogate understood how this “directive” might be interpreted or whether it still communicates the patient’s wishes. In general, EPs should not rely on these indicators to make critical patient decisions.

**CONSENT, DECISION-MAKING CAPACITY, AND SURROGATE DECISION MAKERS**

Respect for patients, the basis for patient autonomy, requires that adults consent before undergoing medical interventions. To give consent, they must retain decision-making capacity. When patients cannot make their own health care decisions, others must make such decisions for them. In such situations, three questions arise: What does “consent” mean in the ED? How can clinicians determine when patients lack such capability? Who then makes the decision?

**CONSENT**

Patients can provide three forms of consent: presumed, implied, and informed. Many patients may provide all three types of consent at different times during a single ED visit. Because clinicians use all three types of consent in EDs, and all are ethically and legally valid, clarifying the differences between them is in order.

The concept of presumptive consent most commonly applies when patients are informed of what will occur and they do not refuse treatment. They allow themselves to be rolled on a gurney to the radiology suite to have a urethral catheter placed, and they remain still while being sutured. The more dramatic ED scenario involving presumed consent is the arrival of moribund patients with grave, often unstable conditions for which a reasonable person would be expected to want treatment. In those cases, clinicians “presume” that rational patients would want treatment. A question that must be raised, however, is whether those patients would want interventions even in the absence of a reasonable chance for meaningful (from the patient’s standpoint) survival. Futility often is discussed from the clinician’s perspective; whether patients would give consent in these circumstances raises the question from the more valid patient’s perspective.

**Implied consent** is operative when patients actively cooperate with the procedure, such as when they extend the arm for phlebotomy or lift the blouse so ECG leads can be placed. Working under presumed or implied consent does not signify absence of patients’ concern regarding the procedure or its complications. Rather, patients may (1) believe they know enough about the procedure to permit it or to cooperate with it without further questioning, (2) be in a condition (e.g., unconscious) in which they are unable to communicate, or (3) feel too afraid (e.g., of the clinician or hospital authority) or uncomfortable (e.g., because of a language barrier) to ask.

**Informed consent** assumes that a patient who has decision-making capacity has been given all pertinent facts regarding the risks and benefits of a particular procedure, understands them, and voluntarily agrees to undergo the procedure. Even if a patient with decisional capacity does not ask about a complex or potentially dangerous procedure, the clinician is obligated to provide information about the associated risks and benefits, unless the patient specifically asks not to be told. In
those cases, the patient should be asked if he or she would like a relative or friend present in the ED to be told. This person need not be the patient’s surrogate but may later help to explain what occurred to the patient.46

Informed consent relates to both law and ethics. Respect for persons is the requirement’s ethical bulwark; statute and common law provide the legal rationale. Physicians have a professional and moral obligation to provide their patients with the information necessary to make informed decisions. Communicating honestly with patients so that they may participate in decision-making is a recent, rather than historical, imperative. Based on a respect for patients, this cooperative physician-patient relationship reverses the paternalism that, since Hippocratic times, has guided physician interactions with patients.46,47

Virtually all states, either in statute or by common law, now require physicians to inform patients about treatment choices and the associated risks and benefits. The legal standard for the information provided is either the “community standard” (also known as the “professional community standard” or the “reasonable physician standard”) or the “materiality standard” (also known as the “reasonable or prudent or subjective patient standard”). The former asks: “What would a prudent physician in the same community, with the same background, training, and experience have disclosed to a patient in the same or similar situation?” The latter asks: “What would a reasonable patient in the same or similar situation need to know to make an appropriate decision?”46,47

Of interest, great variability exists in the legal requirements. For example, although most of the nation’s EDs require informed consent for many regional anesthetic blocks, closed fracture reduction, abscess incision and drainage, lumbar punctures (“spinal taps”), injection of radiocontrast agents and radionuclides for radiography, and nonemergency thoracostomy (chest tube placement), Texas statutes eliminate any requirement to disclose the specific risks or hazards before these procedures are performed.46,48

Decision-Making Capacity

Many ethical dilemmas in emergency medical care dissolve on ascertaining the patient’s decision-making capacity, often linked with consent to (or, more commonly, refusal of) a medical procedure. A basic canon of both ethics and law, as stated by Justice Benjamin Cardozo, is that “[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body ....”49 These situations often can be clarified by an appreciation of what is meant by decision-making capacity and how it relates to consent.

In clinical practice, the word competence often is used to mean capacity. Competence is a legal term and can be determined only by the court. Capacity refers to a patient’s ability to make decisions about accepting health care recommendations. Capacity is always decision-relative rather than global. Although a lucid patient can have the capacity to refuse to have a small laceration sutured, especially if there is evidence of prior refusal without remorse, the same person may not have the capacity to agree to an elective operation or to refuse to have an emergent lifesaving procedure or operation. To have adequate decision-making capacity in any particular circumstance, the person must understand the options, the consequences of acting on those options, and the costs and benefits of the consequences in relation to a relatively stable framework of personal values and priorities50,51 (Box 200-4). Disagreement with the physician’s recommendation is not in itself grounds for determining that the patient is incapable of making a decision. In fact, even refusing lifesaving medical care may not prove the person incapable of making valid decisions if it is done on the basis of firmly held religious beliefs, as in the case of a Jehovah’s Witness patient who refuses a blood transfusion.

**Surrogates**

If patients lack capacity to participate in some decisions about their care, surrogate decision makers must become involved. In most locales, the patient’s advance directive may designate surrogates, or such persons or agencies may be detailed in institutional policy or law. Surrogates often include spouses, adult children, parents (of adults), and others, including the attending physician. On occasion, bioethics committees or the courts will need to intervene to help determine the decision maker.

Children represent a special case. Persons younger than the age of majority (or unemancipated) usually are deemed incapable of making independent medical decisions, although they often are asked to give their assent to the decision, allowing them to “buy in” to their medical treatment plan. In many cases, when determining whether a child has decision-making capacity, the same rules as those that apply to adult capacity are used. The more serious the consequences, the more the capacity to understand the options, consequences, and values involved is required of children to make a decision.9

In the relatively rare case in which a patient has a court-appointed guardian for health care decisions, the guardian’s decisions supersede those of both the patient and any other surrogates. Even if a parent is present, it is not always clear that the adult is acting in the best interest of the child. In such cases, child protective services may need to become involved. Disagreements between parents may, in extreme cases, require the involvement of bioethics committees or the courts.

**Family**

Traditionally, and usually in practice, the family, in particular the spouse, acts as a surrogate decision maker when the patient does not have the capacity to make medical decisions. Yet even when there is a strong family tie, emotional or fiscal costs may sway the surrogate decision maker from certain courses of action the patient would wish taken.

---

**Box 200-4 Components of Decision-Making Capacity**

1. Knowledge of the options
2. Awareness of consequences of each option
3. Appreciation of personal costs and benefits of options in relation to relatively stable values and preferences*

*As part of the assessment for capacity, the patient should be asked about why he or she made a specific choice.

Surrogates make decisions based on two distinct patterns: substitute judgment and best interests. Substitute judgment is used when there is an assumption that the surrogate knows enough about the patient’s values to make a decision similar to that which the patient would make. It is not clear that anyone knows that much about a person to make decisions in every situation.\(^5^2,^5^3\) Surrogates use the best interest standard when they do not know what the patient would want done in a particular situation but, as in the case of Karen Ann Quinlan, they can use earlier statements and behavior to document the patient’s values and then make a decision.\(^5^4\) Some states may require explicit written directives for surrogates to follow.\(^5^5,^5^6\) The best interest standard also applies, as in the Saikewicz case, when the patient has never had adequate decision-making capacity.\(^5^7\) Unless there is already a court-appointed guardian, these situations often end up in court.

**Surrogate Lists**

If a patient lacks decision-making capacity and has no advance directive, many states provide that another person may automatically become the person’s surrogate. In practice, this almost always means that the patient’s spouse may act in that capacity. Some states now have a statutory surrogate list to simplify the process. The most extensive of such lists, which has worked well for nearly 2 decades, specifies surrogates in the following order: spouse (not divorced or legally separated), a majority of the adult children who can be reasonably contacted, parents (of an adult), domestic partner, sibling, close friend, and attending physician in consultation with a bioethics committee.\(^3^7\)

**Bioethics Committees and Consultants**

Multidisciplinary committees have been developed in most large hospitals to consult on cases with bioethical dilemmas and also may participate in surrogate decision making.\(^3^7\) These committees usually have four main functions. First, they coordinate education on bioethical issues involving clinical care for the committee members, hospital physicians and staff, patients, families, and the local community. Second, they help institute mandatory or suggested policies or guidelines for health care professionals regarding decision-making processes in problematic cases and resource allocation. Third, they consult prospectively and retrospectively on clinical cases and offer advice and conclusions to those directly involved, most often concerning the treatment or nontreatment of patients who lack decision-making capacity. Ethics committees usually do not act as the primary decision makers. Rather, its members serve as consultants, providing information, advising, and supporting the primary decision-making role of the patient-family-physician triad. A common consultation relates to urgent decisions about withholding, withdrawing, or continuing life-sustaining medical care. A large part of ethics committee work consists of clarifying the facts and fostering communication.\(^5^9\) Some smaller hospitals have bioethics consultants rather than committees to perform many of the same functions. In 1995, The Joint Commission (formerly the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) began requiring that hospitals ensure that ethics committees’ functions are accomplished.\(^5^9\)

**Physicians**

In the past, physicians made unilateral decisions for their patients, regardless of whether the patients had the capacity to decide for themselves. This still occurs, of course—especially for the acute illnesses and unexpected injuries seen in EDs. There is a tendency for physicians to determine that a patient does not have the capacity to make medical decisions simply because the patient disagrees with the clinician. If the patient’s decision-making capacity is questioned in the ED, the clinician often is forced to make a decision without assistance. But when it is possible to “buy time,” clinicians should consult with colleagues and, if possible, the hospital’s bioethics committee (see Box 200-3). When making unilateral decisions, physicians should recognize that they are not omniscient. Prognoses often are incorrect and medical knowledge is finite.

**Courts**

The courts often act as the final adjudicators of disagreements over medical care. They appoint legal guardians and, in a few select cases, set precedent that is followed as health law. The courts, however, usually are neither expeditious nor necessarily cognizant of bioethical principles. They are instructed only to follow the societal values codified in the law. Many courts have suggested that, whenever possible, health care decisions should remain at the bedside rather than in legal chambers.\(^5^4,^5^6\)

---

**RESUSCITATION ETHICS**

The most time-dependent of all activities and arguably the best training periods in the ED occur during resuscitations. The patients who require this care have implicitly been guaranteed that all appropriate medical knowledge and skill will be brought to bear to attempt to save their lives. This implied promise leads to a dilemma. If the most proficient ED professional always leads the resuscitations and performs procedures, the patient will receive the maximum beneficence, as well as nonmaleficence, as expected. Yet restricting ED practice in this manner also deprives future patients of trained clinicians who could bestow the same beneficence.

This controversy has raged for many years. The appropriate balance seems to be that training in EDs can ethically proceed, as it does in other areas of medicine, if safeguards are provided in the form of on-site supervision by experienced clinicians to ascertain that the patients do receive the best possible and appropriate care. It also has been suggested that medical students and residents could be certified for cognitive and procedural skills in a manner similar to that for other hospital physicians. This certification would enable faculty to know when trainees are capable of performing resuscitations, as well as other medical procedures, on their own.\(^6^0\)

Rarely discussed, but a common practice in some teaching hospitals, has been the custom of allowing trainees with little skill or knowledge to learn and practice procedures on those undergoing resuscitation only when a patient is deemed “unsalvageable.”\(^6^1\) This practice does a disservice to the patient, because prolonging resuscitative attempts solely for this purpose may lead to a clinical state that prolongs dying. It also harms the family and society by making them pay for unnecessary procedures.

**Futility**\(^6^2\)

Emergency physicians, nurses, and emergency medical system (EMS) personnel may, in some circumstances, feel that further medical interventions are “futile.” Yet only three situations meet the most commonly accepted definition.\(^6^2\) The first such situation, which clinicians can identify only in a very limited set of circumstances, is that in which the intervention is effec-
tive in less than 1% of identical cases, based on the medical literature. ED thoracotomy for blunt trauma is a well-documented example. Another common scenario with survival rates approaching zero is that of the out-of-hospital cardiac arrest, either unwitnessed or in a patient who arrives from a long-term care facility. Individual clinicians should not rely on their own experiences to make such decisions, however, because they often are skewed owing to selective memory, limited numbers of similar cases, and other biases.

The second futile situation is physiologic futility, in which known anatomic or biochemical abnormalities will not permit successful medical interventions. Examples of such abnormalities generally accepted by EMS systems as reasons not to intervene or provide transport to hospitals are rigor mortis, algor mortis, burns so severe that the victim is beyond recognition, and injuries incompatible with life (e.g., decapitation). These, along with prolonged normothermic resuscitative attempts without success or prolonged “down time” with an isoelectric ECG, and pulseless electrical activity (PEA) are the criteria often used to help determine whether EMS personnel can pronounce death on the scene. In these instances, EMS need not expend valuable resources in a futile resuscitative effort.

The third situation is that in which the proposed intervention will not achieve the patient’s goals for medical therapy in accordance with the patient’s values. Recognizing this instance, the American College of Emergency Physicians asserted, “Physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient.” Because this course of action is based on knowing the patient’s values related to medical treatment, it is necessary to have talked with the patient in advance (rare in the ED setting), to have received surrogate-supplied information or decisions, or to have access to the medical record. The danger is that differences in values between caregivers and patients may lead to over- or undertreatment. Communication, if necessary using a third party, may help to resolve these issues.

The futility concept should never be used to deny care to dying patients. Even terminal patients experience medical emergencies that require intervention. The goal is to ease pain and suffering. How that is accomplished depends on the patient, the medical condition causing discomfort, and their value system.

**Withholding versus Withdrawing Treatments**

In emergency medicine, a significant difference rightfully exists between the withholding and the withdrawal of life-sustaining medical treatment. The justification for this distinction stems, in part, from the nature of the practice of emergency medicine and the unique manner in which emergency medicine clinicians apply many ethical principles. Because EPs often lack vital information about their patients’ identities, medical conditions, and goals for medical treatment, withholding emergency medical treatment is more problematic than is later withdrawing unwanted or useless interventions. Owing to the nature of emergency medicine, in both out-of-hospital and ED settings, higher standards are required to withhold medical treatment than to withdraw it.

Physicians should begin or continue resuscitation on those patients who arrive at the ED without sufficient evidence to determine that the resuscitation effort will be unsuccessful. The only reason to withhold CPR is the availability of clear evidence, such as a standard advance directive, that the patient did not wish to have this done, or of clinical evidence that further efforts would be futile. Without such information, the presumption must be to intervene.

Once the EP obtains information confirming a patient’s wish not to be resuscitated or indicating a medical condition not amenable to resuscitation, resuscitative efforts and other medical treatment may appropriately be withdrawn. This information may be obtained from an advance directive, a patient surrogate, recent documentation in the medical chart, or EMS communication detailing the failed results of the ongoing resuscitative effort. With rare exceptions, such as after failed suicide attempts, resuscitative efforts should be withdrawn when information is provided either that the patient did not want such efforts or that the patient’s medical condition precludes success.

Many factors influence the potential success of resuscitative efforts, including time to CPR; time to defibrillation, placement of an intravenous line, and first epinephrine dose; time to insertion of first advanced airway device; presence of comorbid illness; prearrest clinical status; and initial arrest rhythm. No combination of these factors, however, clearly predicts the outcome. The most important factor associated with poor outcomes is the duration of unsuccessful resuscitative efforts.

The possibility of a successful resuscitation becomes clearer as time progresses: A patient’s chance of being discharged from the hospital alive and neurologically intact diminishes if spontaneous circulation does not return after 10 minutes of intensive resuscitative efforts. Malpractice concerns have led some physicians to prolong all resuscitation attempts until they reach the point at which there have been no survivors. In reality, cardiac resuscitation with properly executed advanced cardiac life support (ACLS) interventions and documented asystole should not last more than 30 minutes and usually should end much sooner, except in unusual circumstances such as with prearrest hypothermia, after some drug-induced events, following lightning or electrical shocks, or in infants or children with refractory ventricular fibrillation or tachycardia. Without these mitigating factors, prolonged resuscitative efforts are unlikely to be successful.

Three special situations should be noted: (1) Cardiac arrest from blunt trauma is nearly uniformly fatal, so little benefit derives from doing chest compressions for any extended period after the airway is secured. (2) When health care resources are limited, such as during disasters, available resources, such as time, personnel, and equipment, should be devoted to treating those patients with the greatest chance of benefiting. This principle may lead to withholding or more rapid discontinuation of resuscitative efforts than is standard in normal practice. (3) It is unethical to prolong resuscitative efforts to practice or teach procedures or to complete research protocols.

**Palliative Care**

Although lifesaving medical interventions may not be appropriate in all cases, EPs, whenever possible, should provide patients with palliative care. Terminally ill and fatally injured patients have the right to receive state-of-the-art palliative care. Palliation often includes analgesics and may include diuretics, sedation, oxygen, paracentesis or thoracentesis, and other medications or procedures to alleviate suffering. Medical personnel should never withdraw or withhold care; only treatment should be withheld when appropriate. Although medical practitioners, surrogate decision makers, and sometimes patients find it emotionally easier to forgo new interventions than to withdraw ongoing treatment, no orders, policies, or directives should ever prevent EPs from alleviating discomfort.
The purpose of palliative interventions is not to prolong the dying process but rather, when death is inevitable, to make it as comfortable as possible for the patient. As patient advocates, EPs may need to “push” to have the patient admitted to a hospital, hospice, or nursing home, or to get ancillary personnel (e.g., social workers, home health nurses) to intervene for the patient.1

### Notifying Survivors

Death, especially when it is sudden and unexpected, shocks and devastates family and friends. For them, it is a life-changing event, with every nuance burned into their memories. Moreover, although they may not consciously acknowledge it, such losses also may deeply affect ED personnel, despite their almost constant exposure to life’s disasters. This makes death notifications and dealing with the survivors both vitally important and extremely difficult. EPs, who deal with sudden death on a daily basis, are in a position to gain considerable knowledge of and to hone their skills in how to care for the survivors, their newest patients.80

Even though notifying survivors of a sudden, unexpected death is one of the most difficult jobs of the EP’s job, they and other professionals whose job includes delivering news about sudden, unexpected deaths rarely are taught the skills necessary to perform this task. Notifying survivors is emotionally draining—70% of EPs find death notifications to be personally difficult. Perhaps this is because only one half received any type of death-notification education in medical school and only one third received any such training during residency.81

Moreover, most medical “short courses” dealing with resuscitation, such as those on ACLS, advanced trauma life support (ATLS), and pediatric advanced life support (PALS), have not incorporated death notification into their training programs or manuals. This serious omission continues despite the occurrence of approximately 325,000 cardiac disease–related deaths annually in out-of-hospital settings and EDs in the United States.80,82

Occasionally, physicians give the job of death notification to residents, medical students, or nurses. Although all three groups should be present to learn the techniques involved, to have an opportunity to hear what is said, and to observe an attending physician showing sensitivity, they should not be left to do death notifications on their own. That is a form of professional abandonment and, in a teaching hospital, the worst form of student abuse.83

### Viewing Resuscitations

Traditionally, survivors have not been permitted to view resuscitation attempts.80 That attitude, however, is gradually giving way to a more enlightened view based, in part, on recognizing that families gain enormous psychosocial benefits from being present and that they are also patients in need of appropriate support.

The argument against allowing survivor onlookers has been that resuscitations often involve large teams, unclear communications, and team leaders who are unwilling or unable to make firm, timely, and rational decisions.82 Having family members present, the argument goes, introduces the possibility of an onlooker’s fainting or otherwise becoming another patient. Survivors also frequently misinterpret the team’s discussions or actions. Team members may also feel uncomfortable having family members judging their actions.

Yet studies in both the United States and Britain have shown that nearly all survivors who witnessed ED resuscitative efforts found the experience helpful. Seventy-six percent of survivors responded that their grieving was facilitated by having witnessed the resuscitation, and 64% felt that their presence was helpful to their dying family members.85 Psychological tests of survivors who witness resuscitation attempts, performed at 3 and 9 months after the event, showed that this group experienced fewer episodes of “intrusive imagery,” such as flashbacks of the events leading to the death, compared with survivors not present at the resuscitation (relatives in the control group). They also had lower levels of anxiety, depression, post-traumatic avoidance behavior, and grief.86

The American Heart Association now endorses giving family members the opportunity to be present so long as the patient has not previously objected. This position stems from the benefit families can derive from their presence during resuscitation attempts, the lack of harmful effects on them from viewing these resuscitations, and their quasi-right to be there based on the nature of their relationship to the patient.86,87

The presence of these survivors does not hinder the resuscitative efforts and often leads to quieter, more effective team efforts. Experience has shown that survivors who witness ED resuscitative attempts never question whether the team “tried hard enough,” do not ask whether the person is really dead, and spend less time in the ED trying to come to terms with the death. In addition, survivors may actually thank the ED team for their efforts, a situation that rarely occurs under other circumstances, and the ED staff never has to “notify” survivors of the death.

The general procedure is as follows:

1. Ask survivors if they want to view resuscitative efforts.
2. If they do, give them a quick briefing about what they will see, and have a knowledgeable staff member, usually a chaplain, social worker, or ED nurse who can answer their questions, accompany them.
3. Provide a chair for any elderly persons and allow survivors to leave and reenter as they wish.
4. Staff should attempt to cover as much of the patient as is compatible with effective resuscitative efforts.
5. Team members should be advised that family is in the room.
6. The survivors should be encouraged to talk to and touch the patient.
7. Decisions to pronounce the patient dead, although often discussed with the family, generally are communicated in the format of advising them that “we must stop now.” They should never be asked whether to stop the resuscitative effort; this is a medical decision.

Experience shows that the process of having key survivors view resuscitations often works best if EMS personnel notify the receiving hospital in advance of this request. This allows the ED staff to decide whether they will permit it (if it is not policy), to advise team members, and to be ready to provide an escort for the relative to the resuscitation room at the appropriate time.

If the family is present when it is clear that resuscitative efforts should cease, this should be explained to the family before supportive measures are discontinued. This provides them with a chance to “say good-bye” before death is pronounced. Dedicated pediatric EDs and pediatric resuscitation units in general EDs have adopted these procedures more often than others.

### Postmortem Teaching

A less commonly discussed aspect of emergency medicine education programs is the use of recently deceased patients to
teach or practice emergency techniques, such as intubations and central line placement. Although whether this practice is ethical is a matter of controversy, a reasonable argument might be that if medical treatment could not save the patient, then the EP’s responsibility is to hone skills for the next patient in need of expertise in resuscitative techniques. This is not to condone the desecration of a body. Rather, it suggests that because clinicians learned the techniques used during the attempted resuscitation on other dead or living patients, this (now dead) patient owes the next patient the same courtesy. No one would advocate practicing unneeded procedures on living patients, and many people argue against using experimental animals. The religious or ethical beliefs of some ED personnel may make practicing or teaching these procedures in such circumstances problematic.88-91

Resuscitation Research

Physicians in a new and advancing specialty have an obligation to advance the knowledge base from which they practice. This can be done only through research, a significant component of which must necessarily be clinically based. In the United States, federally mandated institutional review boards (IRBs) must approve any research involving human subjects, including research in EDs and, possibly, in prehospital care.92 Increasingly, research ethics committees are being used to approve human-subject research throughout the world. The IRBs try to guarantee that patients who are asked to participate in research review and sign an adequate informed-consent document. Yet even if the patient is conscious, it is unclear whether truly free and informed consent can be given in the midst of a medical emergency.93 In both trauma and cardiac resuscitation research, informed consent is, of course, not feasible. It usually is difficult, if not impossible, to obtain retrospective patient or, if appropriate, prospective surrogate consent. So as not to deny critically ill and injured patients the opportunity to participate in possibly beneficial research trials, the U.S. Food and Drug Administration and the Department of Health and Human Services issued regulations, which became effective in 1996, that allow “emergency research” without informed consent. These regulations contain extensive patient safeguards, including community consultation, public disclosure, and intensive oversight.94

The ethical and legal basis for these regulations is “presumed consent”: If the research is not harmful, and especially if it is potentially helpful, most “reasonable” patients would acquiesce to the research, given the basic values of good and evil (see Box 200-1).95-97 As routinely occurs in emergency medical practice, persons suffering unexpected adverse events with a high probability of rapid death or serious morbidity generally demand that the physician deliver acute care interventions—immediately and without discourse. If there is a chance that the patient could benefit from a therapeutic course of action in such circumstances, most people would demand that it be used. Similar logic applies with acute care research, especially when accepted or standard therapy is futile, and possibly when the investigators believe that equipoise (therapeutic equality) exists between the two tested forms of therapy. Protection for the patient in these cases rests with IRBs, which among other considerations must guard against the possibility of organ-specific success but failure to benefit the entire person, such as producing a patient in a persistent vegetative state after “successful” CPR.

Beyond IRB authorization for research is a moral responsibility for the individual researcher to ensure that the research protocol and its execution are ethical. This responsibility extends to the journals in which the research is published.98

In the main, emergency medicine has an excellent record of ethical research.99

PUBLIC POLICY AND BIOETHICS

Restricted Access to Emergency Medical Care

Society has acknowledged its moral obligation to ensure that everyone has reasonable access to adequate health care.100 People’s need for health care is unequally distributed and highly unpredictable. Few could afford this care if left to their own devices, so mechanisms are in place to share the risk.101

The ethical dilemma for EPs comes in basically two forms: one precipitated by the institution in which the ED is housed and one by outside third-party payers. Some institutions have refused care to patients coming to the ED, sending some away for clinic appointments at a later time.102 Institutions also have pressured EPs to limit treatment, ancillary tests, or hospital admission for patients without the ability to pay. Although such limitation may seem patently immoral, another question must be asked: Is there a moral obligation to the community to keep the health care institution financially viable? Hospitals have closed their doors because of financial losses, and many hospitals, especially in inner-city areas, are on the verge of bankruptcy.

Some prepaid health maintenance organizations (HMOs) use “gatekeepers” to keep patients in need of emergency medical care away from immediate assistance at institutions other than the HMO parent hospital. Moreover, the HMO’s income may depend on not hospitalizing patients, not using ancillary tests, and not permitting ED visits. Nevertheless, it is prudent and ethical for EPs to err on the side of providing for the patient’s needs.

Morality of Triage Decisions

In the aftermath of a massive natural or man-made disaster, triage officers face difficult decisions about who will receive scarce life-saving treatment and who will be left to die without treatment. Even in “routine” ED triage, decisions about who should receive treatment priority and who can wait for treatment may, at least occasionally, have life-and-death consequences.103,104

Triage provides a method to distribute health care resources when patient needs exceed available resources. Triage operates along a continuum of decreasing resources, social order, and the resource-to-patient ratio. Arrival patterns, triage methods, and the applicable ethical basis for triage vary along this continuum.

Most triage systems are designed to serve the values of human life, human health, efficient use of resources, and fairness. Nevertheless, because of the variety of specific triage settings and goals, no single “correct” way to perform or to justify triage can be identified. Routine triage in the relatively resource-rich setting of the modern hospital ED, for example, focuses appropriately on maximizing benefits for each individual patient, giving treatment priority to patients whose needs are most urgent. In triage following a massive disaster, when not all individual needs for lifesaving care can be met, the focus may shift from an individual to a group perspective, and triage officers may seek to save as many lives as possible with the limited resources at their disposal. In special circumstances such as times of war, military commanders may direct that triage systems devote scarce medical resources to achieving a nonmedical goal—namely, military victory. In situations
of complete devastation, the lack of social order and minimal resources may make triage impossible.

Whether the choice of a triage system is justifiable will depend on an evaluation of the specific system itself, its underlying values and principles, and the setting in which it is applied.

**Physician Response to Risky Situations**

Over the millennia, personal values have dictated whether a physician would remain with his or her patients during extreme or catastrophic circumstances. Physicians, even legends of medicine such as Galen, often fled to save their own lives. In the era of modern epidemics of unknown virulence and etiology, it remains a personal moral decision, especially for EPs who are on the frontline of these medical assaults.

How will physicians respond when a catastrophe involving personal risk strikes? The moral backbone of medical professionals may be tested as health care providers weigh multiple factors to determine whether to stay and carry out their professional roles or to step back and decrease their personal risk.

With incomplete information, providers may make decisions based on heated emotions and panic, rather than an accurate perception of risk. The decision to stay or leave will ultimately depend on the individual practitioner’s risk assessment and value system. Professional ethical statements about expected conduct establish important professional standards and norms, but each practitioner will interpret and apply them based on his or her own situation and values. Recent historical precedent suggests that many physicians and other health care providers will dutifully care for the sick and needy, even at great risk to themselves. Although some EPs have worked in dangerous situations, most have not: Nothing in day-to-day emergency medical practice prepares EPs for the great opportunities and challenges that will accompany a pandemic. EPs can, however, reflect on their professional and personal responsibilities in crisis situations, and public and private institutions can create plans for effective communication and care when a disaster strikes. If this can be achieved before the next pandemic or disaster that includes personal risk to clinicians, EPs, who are inevitably among those at highest risk, can be encouraged to “stay and fight.”

**“Proactive Ethics”: How Can Emergency Physicians Change the Rules?**

In every medical system, practitioners find that they repeatedly face identical ethical dilemmas. The normal outcome is an incomplete and often unsatisfactory solution made by administrators, lawyers, bioethics committees, or others. “Proactive ethics” involves changing the rules under which we operate. Easier done in some settings than in others, the process requires that all “stakeholders,” those with a vested interest in an equitable solution, first come to the table and reach a compromise. Such groups often will include physicians, nurses, EMS personnel, lawyers, religious authorities, and representatives of affected groups (e.g., an organization of elderly persons in the case of issues about the aged). Armed with this agreement or even sample legislation that they can present to politicians, it becomes easier to change laws or administrative rules to address recurrent ethical dilemmas. One such process led to a landmark out-of-hospital advance directive law, which markedly lessened unwanted EMS resuscitation attempts. It also led to an extensive statutory surrogate list and a simplified set of advance directives. Proactive ethics lies in the role of public policy—an arena in which EPs are well suited to play a large role.

CHAPTER 201  End of Life

Jean T. Abbott and Susan Stone

■ PERSPECTIVE

The emergency department (ED) frequently is the site of critical turns in people’s health. It is the place where sudden, unexpected deaths occur and bad news must be delivered to survivors. The ED also is increasingly a source of care for patients struggling with chronic diseases, persons in the late stages of life-limited illness, and people actively dying. Palliative care is the medical specialty that is focused on end-of-life care, and some of its principles are being incorporated into the model of the clinical practice of emergency medicine. The integration of quality management of the dying patient into emergency medicine practice presents challenges but also offers communication and negotiation skills that can be used by emergency physicians in many aspects of their practice.

Death in the ED differs from death in other areas of the hospital in several ways: (1) deaths often are unexpected; (2) the patient and family and their values often are unknown to ED staff; (3) trust needs to be established rapidly; and (4) management decisions often must be based on limited medical information. These factors contribute to stress for the emergency care team in managing the first few minutes of a critical illness. The initial response to life-threatening presentations in the ED must be to treat aggressively and resuscitate persons in extremis in the absence of knowledge that this is counter to patient wishes. Much of the core of emergency medicine is devoted to preventing untimely death in people with severe trauma, a “heart too young to die,” or another sudden, unexpected life threat. However, when resuscitative and rescue efforts fail, when patient wishes to forgo further interventions become clear, or when the natural end to life comes, the emergency specialist should be prepared to withdraw unwanted treatments, to make the patient comfortable, and to lead the staff and the patient’s loved ones in giving the patient’s death the meaning and respect it deserves.

■ PRINCIPLES OF DISEASE

Epidemiology of Death and Dying

One hundred years ago, the predominant pattern of dying was a rapid, precipitous death from infectious diseases and accidents. With modern medical advances, chronic diseases have become part of the last years of life for most people. Three diseases—heart disease, cancer, and stroke—accounted for 60% of deaths in the United States in 2000, whereas unintentional injury accounted for only 4% of deaths. Most people live with some limitation in their ability for self-care for 2 to 4 years before they die. Four common trajectories of dying have been described (Fig. 201-1). Sudden death (due to cardiac arrest, trauma, or other sudden event) occurs in only 15% of people. The other trajectories are more common and occur with roughly equal frequency. The predictable decline in patients with “terminal illness” over 6 months or less provided the basis for the hospice concept of managing the dying process for patients with cancer and terminal AIDS. In cases of organ failure (e.g., chronic obstructive pulmonary disease [COPD], heart failure, renal failure, and other progressive serious medical diseases), gradual decline is punctuated by intermittent exacerbations (entry-reentry decline). The time of death for people with these progressive and ultimately fatal diseases is not very predictable, and it often happens rather unexpectedly during an acute deterioration. These patients frequently are treated for acute deterioration in EDs. The fourth trajectory of gradual decline, or “frailty,” is associated with some form of dementia in 50% of affected persons and a lingering course that can extend over many years, stressing and wearing out caregivers and other support systems as decline in functional abilities progresses.

Several end-of-life skills are important in the practice of emergency medicine. One of these is to rapidly determine, when possible, the patient’s wishes for interventions at a time of crisis. Wishes may be transmitted through written advance directives or direct conversation with a patient or proxy about general values or specific management choices that should guide ED management. Invasive interventions may carry greater risk and be less beneficial near the end of life, and patient choices may include spiritual, economic, and community factors that the emergency physician cannot know without clear, rapid communication and establishment of treatment goals. Likewise, the patient or the surrogate needs the best information possible about the medical and technical aspects of a critical turn.

Studies have shown that physicians may be overly optimistic regarding prognosis, particularly if they know the patient well. Patients and families need to understand prognosis in order to make decisions about what treatments they want and to plan priorities for their remaining life. Functional status is a strong indicator of a patient’s prognosis; decline is associated with increasing likelihood of death, particularly in patients with terminal cancer, for which the dying trajectory tends to be most predictable. For other end-stage diseases, however, validated scales to predict survival are commonly used in palliative care.
assessments. In the ED setting, rapid assessment of the likely prognosis in a particular case can be accomplished by eliciting information about the patient’s ability to perform activities of daily living (ADLs) (i.e., “performance status”). When a patient is not able to spend time out of bed, has reduced appetite, and cannot dress or bathe without assistance, he or she is likely in the last months of life. Such a patient should be eligible for the Medicare hospice benefit. This is the time to involve hospice or palliative care consultants in the ED or during hospital admission. If a patient has already “enrolled” in hospice, it is important to contact the relevant hospice program (accessible around the clock) from the ED before making treatment and disposition decisions.1,4,6

In Western culture, death has become “medicalized” over the last 50 years.7 Modern technology often has allowed human control over the timing, site, and pace of dying. Death occurs in an institution for approximately two thirds of people.8 Frequently, the dying process is accompanied by invasive diagnostics and medical interventions, even when death is expected and these interventions may increase suffering at the end of life. Death often is seen in modern society as the failure of scientific know-how to keep people alive, rather than the natural end to a life. When death is approached with less fear by both patients and physicians, it is possible to help patients and families make the best of the time remaining to them and to deal with death as the natural ending of life.

Definitions of Death

Biologic definitions of death are currently the subject of considerable debate. Twenty years ago, cardiorespiratory failure defined death, because this was rapidly followed by brain death (which could not be directly measured) caused by failure of oxygenation and perfusion. Death was a distinct biologic event, because all vital systems stopped when one of them failed.

Currently, cardiopulmonary “death” is not necessarily inevitable or irreversible. Ventilation can be maintained externally, and even circulatory support through pharmacologic means or pump assist can sometimes buttress an inadequate heart. Because of this, a second pathway called “brain death” has been conceptualized. The brain-based determination of death is derived from the irreversible failure of clinical function of the whole brain, manifested by apnea, profound coma with unresponsiveness, and absence of brainstem reflexes.9 The most common causes of brain death in adults are traumatic brain injury and subarachnoid hemorrhage. In children, the primary causes are accidental or nonaccidental trauma and asphyxia.10 Although the consequences of these events are seen with some frequency in the ED, the criteria and irreversibility standards for brain death are seldom met in the first hours after the resuscitative effort. One additional impetus for development of a concept of brain death was the need to define a biologic and ethical boundary to life for procuring organs for transplantation. Declaration of brain death allows harvesting of organs while continuing cardiopulmonary support and organ perfusion and currently accounts for more than 90% of organs harvested from deceased donors.11

In addition, a new protocol designed to increase the pool of organ donors and acknowledge the rarity of complete brain death defines “non-heart-beating” organ donors. Such patients have a dismal prognosis for meaningful survival but will not sustain complete brain death until the time of cardiopulmonary arrest. Pulmonary and cardiac support is withdrawn, death is declared after an interval of several minutes, and organs can be harvested with a minimum of warm-ischemic time.10,11 The issues surrounding society’s definitions of death are complex, and the struggle with attempts to balance respect for persons and their bodies with the need for transplantable organs is expected to continue.

It is important for physicians to be clear about medical language relating to death. The patient is allowed to “die naturally” when the ventilator and cardiac support are removed. A patient who is declared “brain dead” is dead even though the person may appear to be alive, with pulse and chest rise, to the family. A patient in whom “higher” brain function or cognition is lacking is not considered to be “dead” since “whole brain” death requires failure of the brainstem in addition to cortical function. The confusion over medical definitions of death is made greater by cultural and religious variations in conceptions of death. The different criteria also can lead to suspicion among the public that these definitions are “mal- leable” and serve physician agendas, rather than respecting the patient. In the ED, cardiopulmonary death is the only death that can be recognized. Use of the term brain dead is to be avoided.12 Brain death requires time and strict criteria to diagnose. However, the emergency physician has an important preparatory role in delineating the status of the patient who is breathing and who has a pulse (perhaps from a successful resuscitation effort) but may ultimately die a brain death. It is very helpful to introduce the family to concepts of prognosis, brain injury, and the further steps that will occur over the succeeding hours that will give physicians and family a clearer picture of whether an injury or insult is fatal or not.

Related Issues

Futility

Physicians are not required to offer treatments that are not beneficial.13,14 Unfortunately, information available in the out-of-hospital setting or the ED often is insufficient to make the judgment that a particular patient’s condition is “terminal” or that treatment efforts would be “futile.” In the case of cardiopulmonary resuscitation (CPR), the emergency physician proceeds with full resuscitative measures unless there is a clear
understanding that this is contrary to the patient’s wishes. Although the term “futility” can be a nontechnical expression of a physician’s assessment that a proposed intervention is nonbeneficial, the definition is unclear and the term is best avoided in medical discussions of critically ill patients. Futility may mean treatment for which no survivors have been reported in similar circumstances in well-designed studies. Other definitions attempt to quantify futility as a less than 1% chance of meaningful survival. Rarely does the emergency physician have information about the patient’s overall condition that would allow such a determination, even if the physician were to accept the quantitative definition, which continues to be debated. The term futility also can be used qualitatively, implying that “meaningful” life will not result from the proposed intervention. This use of the term is likewise problematic because it is a unilateral judgment about values that a patient and family may or may not hold about what constitutes “life.”

Quality of Life and a “Good” Death

As technology gives physicians the ability to stabilize patients with serious and noncurable diseases and to manipulate the timing of death, and as people are increasingly exercising their autonomy in deciding how to control their dying, more conversations are occurring about what constitutes a “good death.” There is evidence that the quality of life for persons who live into their 80s is better than it was 20 years ago. For that, medicine can be proud. But there are also serious deficiencies in end-of-life care. A majority of people wish to die at home, although nearly 70% die in an institution. In the famous Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) of more than 9000 patients with life-threatening diseases and a 6-month mortality rate of approximately 50%, only one half of the physicians knew when patients did not want CPR. In addition, families in that study reported that one half of the conscious patients were experiencing significant pain at the time of death.

In the ED, resuscitation is performed unless patients’ wishes to the contrary are clearly known. Information that CPR, intubation, or other invasive treatments are not desired can be conveyed in the form of written advance directives, a state-authorized “no-CPR” or do-not-attempt-resuscitation (DNAR) directive, clear indications from the person assigned the patient’s durable power of attorney for medical affairs, or communication with the patient’s physician. Unfortunately, fewer than one fourth of people have prepared advance directives of any type. Evidence of wishes from prior conversations between patients and family or physicians also are uncommon and are rarely available in an emergency situation. The lack of knowledge regarding patients’ wishes is particularly worrisome because most people—both patients and surrogates—do not understand what “do everything” means. Family and other surrogates also are poor at predicting care that their loved one would want or not want. In one study comparing patient and surrogate choices about life support, surrogates guessed patient wishes only 59% of the time, little better than chance. The best predictor of accurate knowledge of patient wishes in that study and others was a specific discussion between the patient and surrogates about values and wishes.

In patients with severe disabilities, physicians and other health care providers likewise have a difficult time judging quality of life and patient wishes at the end of life. Gerhart and colleagues surveyed emergency care providers’ hypothetical attitudes toward quality of life after spinal cord injuries and compared their responses with those of high-level spinal cord injury survivors. Only 18% of providers (e.g., emergency medical technicians, nurses, and physicians) imagined they would be glad to be alive after a severe spinal cord injury, whereas 92% of survivors were glad to be alive. Eighty-six percent of the quadriplegics felt that their quality of life was average or better, whereas only 17% of emergency care providers predicted they would have a similar view of their quality of life in the same condition. It is important to remember that people’s assessment of what is a “good life” changes with time, age, and the realities of illness.

What priorities most commonly occupy patients at the end of life? When death is near, patients have both medical and nonmedical concerns about their dying. Singer and associates suggest that five topics predominate in people who are dying: having pain and other symptoms adequately relieved, avoiding inappropriate prolongation of dying, achieving control, relieving others of the burden of their dying, and strengthening personal relationships. The only way to know what is important and what brings joy to patients’ lives, particularly in the face of chronic or disabling disease, is by asking patients and those close to them. Most patients want to know prognostic information, although this preference should be ascertained before such information is given. Realistic hope in the dying patient usually centers on desires for dignity, management of symptoms, and resolution of key relationships.

The Goals of Medicine

Medical authorities and philosophers have long debated the proper goals of medicine. Physicians are most familiar with the goal of “curing” diseases. Ellen Fox reminds us of the complexity of our task in medicine: “Although cure is unquestionably an appropriate goal of medicine, other goals are important as well: promoting health, preventing illness and injury, restoring functional capacity, avoiding premature death, relieving suffering, and caring for those who cannot be cured.” In Western society, the curative model predominates, and physicians are rewarded for being analytic and rational. The disease, not the person, becomes the object of analysis. Symptoms are clues to diagnosis rather than problems to be treated in and of themselves. Fox points out that the palliative care emphasis on “relief of suffering, control of symptoms, and restoration of functional capacity” is really just one end of a spectrum of care that a physician provides. Most patients with life-limiting conditions have reversible elements to their disease process; likewise, even the patient with streptococcal pharyngitis wants symptom relief in addition to cure. So the goal of medicine may be to discern where to place the emphasis for the patient: The curative and the palliative models need to be balanced in varying proportions to optimize care for the individual patient.

If the physician is to achieve the goal of relieving suffering, he or she needs to understand the difference between pain and suffering. Eric Cassell first introduced the idea that a primary goal of medicine was the relief of suffering in a landmark article in the New England Journal of Medicine in 1982. Cassell emphasizes that pain happens to bodies, but that suffering happens to persons. Suffering derives from the meaning behind the pain or other symptom. It is unique to each person and can only be understood from the patient’s perspective. Suffering is “the state of severe distress associated with events that threaten the intactness of the person.” Patients may be in severe distress without any physical pain; others may experience their pain with very little distress. Patients suffer, as Cassell points out, “when they feel out of control, when the pain is overwhelming, when the source of the pain is unknown, when the meaning of the pain is directive, or when the pain is chronic.”
The World Health Organization defines palliative care as “an approach that improves quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual.” Palliative care usually consists of an interdisciplinary team of experts that offers various support systems for patients and their physicians near the end of life and can provide inpatient care or consultation, as well as patient management in hospice, in long-term care facilities, and in homes. Examples of some acute palliative care interventions that can be applied in the ED are described at the end of this chapter.

_Hospice care_ is the aspect of palliative care for patients who are likely to be within 6 months of death. The hospice movement, which started in England in the 1950s, initially sought to provide a haven of medical care for persons dying of cancer. Home and inpatient hospice programs now exist throughout the United States and are funded through Medicare. If a clinician would “not be surprised if a patient died within six months if the disease ran its natural course,” a hospice evaluation would be appropriate. The patient is “hospice eligible” if hospice judges that the patient’s lifespan is likely to be less than 6 months and Medicare will certify a patient for hospice. Currently, hospice care is provided for an expanded spectrum of end-stage illness, including cancer, organ failure (e.g., heart, liver, kidney), neurologic diseases, and terminal AIDS.

Confusion about eligibility for hospice care contributes to late referrals. Only approximately 20% of patients die while receiving hospice services, including less than one half of patients with cancer. Referrals occur a median of 20 days before death, leaving insufficient time for many of the services that hospice can offer. Although physicians may have difficulty quantifying a patient’s likely lifespan as less than 6 months, prognostic tools exist, and enrollment criteria are based on (1) lack of curative intent as well as (2) progressive decline in function.

The palliative care movement has developed as an expansion of end-of-life care to include not only hospice-eligible patients but also patients with incurable, debilitating chronic noncancer illnesses (e.g., COPD, congestive heart failure) that require symptom control but with a less clear course to death. Even though the prognosis at any point in time is uncertain, these diseases are not curable, and goals of care may be better served by switching primarily to enhancing the quality of remaining life for affected patients, keeping them as active as possible, and controlling symptoms. These patients are best cared for by palliative care experts. Palliative care consultation offers patients a mechanism to discuss and review management of symptoms and medical interventions that patients desire or wish to avoid in managing their living and dying with severe chronic diseases, with hospice referral when this is desired and possible.

In 2006, the American Board of Emergency Medicine joined with nine other specialty boards to cosponsor the American Board of Palliative Medicine. This alliance has recognized the real need of emergency physicians to address a wide range of interventions and management decisions that are specific to the end of life. The integration of emergency medicine and palliative medicine has stimulated educational efforts to define the scope of ED-based palliative care and curriculum design.

**Emergency Medicine and End-of-Life Care**

Emergency physicians encounter death more frequently than physicians in many other specialties. Resuscitation and restoration to functional living will always be a primary goal of practice and research in this field. However, seriously ill patients treated in the ED often present with important but less emergent complaints. The physician often does have time for deliberation about choices of care through conversations with patients or family. Even when a patient has a severe chronic disease that is not curable, interventions are available that can improve the quality of life. Also, at the end of the course of chronic disease, death is not always unwelcome. Addressing the needs of patients and their families at these critical times requires a complex set of skills. The rest of this chapter is devoted to out-of-hospital end-of-life concerns and to the aspects of end-of-life care that should be part of every emergency physician’s skill set: delivering bad news, death notification, establishing and honoring patient goals of care and advance directives, symptom control, and palliation.

## SPECIFIC DISORDERS AND CONCERNS

### Out-of-Hospital Considerations

Historically, out-of-hospital systems were designed to provide immediate resuscitation, stabilization, and transport of seriously ill or injured persons to EDs. Aggressive and early resuscitation, through CPR, airway management, defibrillation, fluid resuscitation, and trauma stabilization, has resulted in significant benefits and reduced mortality in patients with critical illness for whom survival is time-dependent and potentially reversible causes of illness or injury threaten life.

Emergency medical service (EMS) systems also are called to transport patients who have died or to assist patients who are in extremis but whose death is expected. As well, EMS is activated for patients with acute decompensation of chronic medical conditions such as heart failure or COPD, and for symptoms that occur in the context of terminal conditions when caregivers at the scene cannot cope. Patients at the end of life may desire aggressive interventions for acute exacerbations of chronic illnesses, or they may prefer only supportive care or transportation to achieve a nonviolent end to their life. In emergency situations, it may not be possible to determine the patient’s underlying medical conditions or where the patient is currently on the arc of living and dying. In some situations, a titrated response is possible, and noninvasive supportive care (such as positioning, suctioning, oxygen, or mask ventilation) during transport can buy time until further evaluation in the ED can clarify the patient’s goals of care.

### Field Death Pronouncement

Several physiologic circumstances have been identified in which out-of-hospital providers should not initiate or continue CPR because of uniformly poor outcomes and no benefit from intervention. American College of Emergency Physicians (ACEP) and American Heart Association (AHA) guidelines state that CPR should not be initiated in patients with nontraumatic cardiac arrest and signs of irreversible death, such as decapitation, dependent lividity, or rigor mortis. ACEP policy recommends discontinuing resuscitation in the out-of-hospital setting if the patient remains in asystole or wide-complex pulseless bradycardia after a trial of adequate resuscitation, including CPR, intubation, medications, defibrillation, and pacing. The National Association of Emergency Medical Services Physicians (NAEMSP) supports this approach. Termination of resuscitation efforts in nontraumatic cardiac arrest patients should be made in agreement with online medical direction and predicated on access to witnesses...
or family, provider comfort with death notification and grief counseling, and safety and logistical considerations. If questions arise about resuscitation, CPR and ACLS measures should be initiated and the patient transported. It can be easier and ethically more sound to withdraw care in the ED than to withhold care at the scene.

Honoring Advance Directives to Withhold Resuscitation

There is an increasing movement to develop policies that allow EMS providers to honor patient wishes not to receive interventions at the end of life, even when resuscitative measures might succeed. The 1991 Patient Self-Determination Act recognized that health care providers must honor informed decisions by patients who wish not to be resuscitated. Most providers have experienced situations in which attempted resuscitation is later determined to have been against the patient's wishes. In a Seattle review of out-of-hospital cardiac arrests in which all patients received full resuscitative efforts, 7% of patients were ultimately determined to have had "unwanted" resuscitation, and 25% of patients experienced resuscitation in the context of severe chronic disease.

Identifying valid directives to withhold CPR or intubation is problematic for out-of-hospital providers. Information about patient wishes and underlying diseases is frequently confusing. DNAR requests may be difficult to validate, and rapid intervention is frequently required. Many state-based programs have been developed to try to identify patients requesting no CPR through bracelets or official registered forms on their persons, allowing supportive care but no resuscitative efforts if the patient experiences cardiopulmonary arrest.

The ACEP has recognized the difficulties with respecting patients' desires to forgo resuscitative efforts and issued guidelines for developing out-of-hospital DNAR policies. In some states, statutory authority for EMS personnel to honor DNAR orders has been developed, but provisions vary widely. Written statements or identification bracelets must be consistent, easily recognizable, legally acceptable in that state, and clear about what resuscitative measures the patient would and would not wish to receive. A family member or friend who is present at the scene and has valid medical durable power of attorney for health care documentation also may make decisions to initiate or refuse treatment measures on behalf of the patient. The most widespread initiative to provide out-of-hospital written directives to limit life-sustaining care is the Physician Orders for Life-Sustaining Treatment (POLST) Paradigm program in Oregon, which uses a clearly recognizable pink form posted on the home medicine cabinet to identify a range of patient wishes near the end of life. This program is being adopted in other states.

Several concerns about the validity of written advance directives persist: Patient wishes can change over time, nonstandard forms of DNAR requests (such as "medical alert" bracelets, notes on prescription pads, or tattoos) cannot be recognized, and a theoretical concern is that relatives or bystanders may not be accurately relaying the wishes of the patient. In one survey of emergency medical technicians (EMTs), more than 20% had experienced ethically conflicts over the execution, honoring, or validity of DNAR wishes or orders at the scene. On the other hand, most out-of-hospital providers agree that it is appropriate to withhold resuscitative attempts in terminally ill patients.

Honoring Verbal Requests to Withhold Interventions in the Field

In most EMS systems, verbal requests to limit resuscitation are not accepted, because of the concern that out-of-hospital providers cannot confirm that these represent the patient's current wishes. In view of the incidence of "unwanted" resuscitation, King County in Washington State has introduced a new protocol of allowing EMTs and paramedics to withhold resuscitation in situations in which family or caregivers indicate that no resuscitation is desired and the patient has a terminal condition (i.e., death is expected and the patient is under a physician's care). EMS personnel do not need direct physician approval to forgo resuscitation. The incidence of non-initiation of resuscitation increased from 5.9% to 11.8% in EMS services adopting the expanded standards. Other regions are testing this protocol, which must be accompanied by population buy-in and legal protections against errors. No adverse consequences have resulted so far, although wrongful death suits remain a theoretical concern. EMS provider comfort level with expanded standards has been high.

Attempts to honor patients' requests at the end of life should be a goal for both out-of-hospital and ED personnel. Out-of-hospital providers need to be aware of the standards for honoring DNAR requests in their respective states. In addition, providers need to be knowledgeable about types of advance directives and surrogate laws for the state in which they practice. In most EMS systems, field pronouncement of death requires physician base-station consultation. Unilateral EMS provider judgment not to start resuscitation has been reported, but snap judgments that patients are "terminal" are not necessarily accurate and should not be the sole criterion for withholding interventions.

Supportive Out-of-Hospital Treatments near the End of Life

Patients at the end of life can benefit from supportive or palliative treatments at the scene and during transport. Positioning, suctioning, and administration of pain medication and oxygen for dyspnea all may be important to maximize patient comfort. Before an intravenous line is established, EMS personnel should ask the patient's permission to do so, because even the pain associated with insertion of the line may be counter to patient wishes. If the patient is being transferred from a long-term care facility to the ED, all care instructions, CPR directives, advance directives, and contact names and numbers are carried with the patient, because these will help guide continuing care in the ED.

Management of Hospice Patients

Although hospice care protocols are written to avoid activating the EMS system, scenarios routinely arise in which the patient is in the dying process and family members panic or cannot handle some terminal situation. There may be anxiety in the last hours of life, a feeling of helplessness, or concern for the patient's perceived or real suffering. There may also be disagreement between family members about the best way to help the dying person. The family may request death pronouncement at home, but out-of-hospital providers should involve medical control to affirm this if necessary. Transport and comfort care should always be offered if the family wishes or if the setting appears uncomfortable for those involved in the dying process.

Special Issues in the Out-of-Hospital Setting

Suicide

Although respect for patient wishes is a core value in today's society, suicidal patients frequently are impaired. Modern belief holds that suicidal depression usually is treatable. Patients near death from suicide should receive full resuscita-
tive efforts unless there is a specific exception, such as physician-assisted suicide in Oregon, with formal documentation and an alternative protocol for out-of-hospital providers to follow. If the patient is dead and meets criteria for not starting resuscitation, the coroner or medical examiner should be notified. The scene needs to be protected to allow an investigation, if needed, because the history is rarely clear or complete during the emergency call. Decisions should be made after consultation with the medical control physician.

Pregnancy
In the case of a pregnant trauma patient, fetal survival is best ensured by aggressive care of the mother. Some unborn babies will die despite major or minor maternal injuries, but field rescue of the baby after the mother is pronounced dead is rarely appropriate and not advised without physician control. A pulseless woman in the third trimester of pregnancy should be transported to the nearest ED capable of performing a perimortem cesarean section for attempted resuscitation of both mother and baby.

Pediatric Deaths: Sudden Infant Death Syndrome
Death of a child is among the most difficult of human experiences. With pediatric deaths, regardless of the cause, a complete resuscitation regimen, including transport, is appropriate. Child abuse should always be considered as a possibility. Transport may be done more for the psychological benefit to the family than in the hope of survival. As sudden infant death syndrome has become more widely recognized and understood by the public, some families wish to avoid “extraordinary measures” of resuscitation once the diagnosis is recognized and the outcome is inevitable. Many desire to be with their infant in his or her last moments. Out-of-hospital personnel should respond to these requests with understanding and compassion; however, the site of pronouncement of death should be in the hospital for almost all pediatric deaths.

Death in the Emergency Department
Delivering Bad News
Every emergency physician will be required to communicate bad news to patients, family members, and caregivers. The manner in which this is done may make a difference in the course of subsequent grief and coping. Compassionate communication can strengthen trust and foster collaboration in planning between the medical team and the patient and family. Emergency physicians have particular challenges in delivering bad news in that they do not have ongoing relationships with their patients and because the bad news may be abrupt and unexpected. However, the newness of relationships in the ED also may allow a more frank and open conversation about a patient’s illness, prognosis, and wishes, particularly when the sudden downturn precipitating an ED visit is part of a severe chronic disease.

The goal of skillfully breaking bad news is to reduce the severity and the duration of stress and encourage engagement of coping mechanisms, both for physicians and for patients and their caregivers. According to a theoretical construct proposed by Ptacek and Eberhardt, staff and physician stress often peaks just before transmission of the bad news, whereas patient or caregiver stress emerges after delivery of the bad news. Physician stress correlates directly with the severity of the news, as well as any responsibility for the outcome that the medical team may feel, and inversely with the amount of experience delivering bad news. Many providers feel inadequately prepared for death disclosure or delivery of bad news about a new diagnosis or turn in health status for a patient with a life-limiting illness. Skilled resuscitation, diagnosis, and treatment of patients are key to keeping the external sources of provider stress manageable. Reduction of the anticipatory stress of delivering bad news may occur with use of a structured protocol, practice, planning the physical and social aspects of the setting, and other methods of enhancing experience. Experience with revealing medical error or other aspects of responsibility for outcomes has not been well studied.

Several initiatives to improve delivery of bad news have been introduced. These encourage training in communication skills, explicit instructional sessions, role playing, use of standardized patients, and observation of colleagues who are comfortable with this aspect of patient care. Little research has examined the best methods of increasing patient and family satisfaction with this important aspect of patient care. Physician coping mechanisms may or may not be helpful to patients, but much still needs to be learned about how to be most helpful in this difficult time for patients. If the physician develops patterns to insulate himself or herself from stress that involve lack of sensitivity to the receiver’s needs, he or she may cause greater stress to the receiver by use of vague language, delegation to others, or delaying or rapidly disengaging from the encounter.

For the patient and family, the ED typically is the place where bad news is sudden and unexpected. This can certainly make the strain even more severe and overwhelming. Trust between ED caregivers and critically ill patients or their survivors, who were unlinked strangers just a few minutes before, does not come easily. Whereas providers may focus on the content of the information they must convey, patients focus more on the process. Surveys of patients and families have identified the following factors as desirable for receiving bad news: privacy when receiving news, the ability to express emotions safely, information that is free of unclear language or medical jargon, empathic and caring attitude, allowance for hope, and ability to ask for and receive good medical information. One technique for encouraging provider empathy is to structure a conversation according to the NURSE pneumonic: The provider names the emotions observed, confirms whether this understanding of the receivers’ feelings is correct, expresses verbal and nonverbal respect for the receivers’ feelings, supports them through expressions of concern, understanding and willingness to help, and explores additional concerns.

The steps listed in Box 201-1 and explained in detail in the following paragraphs are designed to shape the interaction to facilitate the patient’s or survivors’ work through this stress and movement toward coping. This six-step template was adapted from Buckman’s work and adopted also by the Educa-

---

**BOX 201-1 DELIVERING BAD NEWS**

The steps listed below can help you think critically about how best to communicate at a time when stress is high. See the text for details about each step.

- **Step 1: Physician preparation**
- **Step 2: What does the patient know?**
- **Step 3: How much does the patient want to know?**
- **Step 4: Sharing the information**
- **Step 5: Responding to feelings**
- **Step 6: Planning and follow-up**

tion for Physicians on End-of-Life Care (EPEC) teaching project. Key to moving through the process of delivering bad news is the “ask-tell-ask” interactional framework in which the physician is guided by the patient and family in regard to the pace, amount of information, and style that will work best to let them feel and hear what they need.

**Step 1: Physician Preparation**

Before the physician interacts with the family or patient, preparatory steps are important. These include confirming all medical facts of the case, clarifying the name of the patient, being aware of any uncertainty about the patient’s identity, and knowing the relationships between the patient and those with whom one will be talking. The physical site for the conversation should be quiet and allow for private exchange of information and safe expression of emotions. Sometimes this is difficult in the ED, but a family room or other quiet area usually is available to use. If the patient can be included, moving the patient to a private area may be possible, or key members of the patient’s support group can be gathered around the bedside.

Physicians should identify themselves and their position, directly address the patient (when present) or the key persons receiving the news, and refer to the patient by name. Before beginning the discussion, the physician should sit down close to the patient, make direct eye contact with the patient (or close relatives), and be physically and mentally open to their concerns and needs.

**Step 2: What Does the Patient Know?**

It is useful to know what the patient or family understands before the delivery of news. An introductory question can be used, such as “What do you understand about your illness?” or “What have you been told happened to [name of spouse/sibling/other]?” This information helps the physician to see the event as the patient and family are seeing it thus far and to adjust the mode of delivering this news to their understanding. In the ED, when patients and families may expect “the worst,” this tactic can be perceived as delaying. In a less critical situation, however, asking about previous testing, conversations with physicians, and understanding of the patient’s illness can help the subsequently delivered information fit into the patient’s perspective and expectations.

**Step 3: How Much Does the Patient Want to Know?**

Every patient has the right to accept or refuse medical treatments based on informed consent. This also is true for information. Most patients appreciate the direct, simple truth about their condition and prognosis. There will, however, be some patients who do not want to receive the information that the provider is about to deliver. These patients may wish to designate a friend or family member to represent them. This choice should be respected if possible. It is important to remember that people process information and make decisions in many different ways, based on their own cultural and religious views and previous experiences. The Western principles of truth-telling and individual decision-making are cultural values and may be foreign to some families and communities.

Sometimes the family learns of a diagnosis and prognosis before the patient does and requests that the patient not be told. The physician’s alliance with both patient and family is important, although responsibility to the patient is primary. Physicians should explore why families do not want the patient told bad news: Is it a cultural tradition? Are they afraid of what harm it will cause the patient? Have they had previous bad experiences? The physician is still required to ask the patient how much he or she would like to know. Sometimes it is helpful for the physician to invite family members to be present for this discussion. This important information should be learned or asked using an independent interpreter (rather than a family member) if the patient does not speak the same language as the physician.

**Step 4: Sharing the Information**

In general, patients and families want to know bad news in a timely fashion. This is sometimes uncomfortable, particularly when important information may not yet be known—a common occurrence in the ED. At the very least, it is recommended that patients and family be given a preparatory warning after introductions, such as “I am afraid I have some bad news.” In delivering the information, it is important to use simple nonmedical language and to make sure that the patient comprehends the information. Space should be allowed for patients and family to absorb the news, to react, and to begin to ask questions. The patient and family stress response will lag behind that of the physician, because the physician has had at least a few minutes to adjust to the current situation, but the family has not.

Although using the phrase “I’m sorry” can be a reflection of empathy, it can be misinterpreted. Some physicians have suggested using expressions such as “I wish things were different” instead, as a sign of solidarity. Providing survival data when the discussion is about a severe or terminal diagnosis may be better reserved for a later time, but it is important to know how to access this information. The physician’s message should include some realistic hope and also reassurance that the patient will not be abandoned by the medical care team, even when cure or survival is unlikely.

**Step 5: Responding to Feelings**

The reaction to bad news often is unpredictable and can range from sadness to rage. It is important for ED clinicians to be aware of the wide varieties of responses that will be seen. The patient and family should be allowed to express their feelings, even if this is uncomfortable. Acute grief is painful but important. The emergency physician must be prepared both for persons who turn inward and those who rage outwardly. Practicing and reflecting on these situations will allow the physician to deliver bad news and support the survivors. In the ED, it often is helpful to invite members of the team into this meeting (e.g., social worker, nurse, or chaplain) who will not be pulled away to other care needs, can provide emotional support, and can help the family navigate through the early stages of grief, as well as the technical details necessary.

**Step 6: Planning and Follow-up**

The ED is an entry point into the hospital if the patient survives. Family members should be encouraged to stay with the patient, particularly if it is possible that the end of life is near. Prognosticating may be difficult, in view of the limited information that can be obtained in the initial assessment. When initial management has stabilized a patient with an acute, critical condition, it may be appropriate to look ahead to decompensation that could occur later in the hospitalization. Some experts have suggested a “hope for the best and prepare for the worst” kind of conversation. The physician can share the success, however transient, of any ED interventions and the positive news and hope that this provides. At the same time, he or she can prepare the patient or family for the possibility of later setbacks and have them consider what actions may or may not be appropriate if “the worst” happens. If the patient does not have written advance directives, the emergency physician can facilitate the conversation, initiate written wishes, or at least advise the patient that the admitting physician will need to
have an early conversation about future plans and goals for the patient. The physician should assure the patient and family of what the next steps will be, including hospital admission or discharge from the ED, consultation with specialists, support group referral, or chaplain services. It is important to make sure that the patient and family do not feel abandoned. Even when dying is near, providing active care and comfort is a major task for the medical team.

Death Notification

One of the most difficult forms of “bad news” to deliver is death notification. Emergency physicians need to practice this skill specifically (Box 201-2). In general, the format can follow the guidelines for delivering bad news from Box 201-1. With death notification, however, diagnosis is certain, and actions required are more definite. Families do not have time to adjust or think about options, and the message is more stark.

Death notification usually occurs after an unsuccessful resuscitation attempt. Physicians should be sure they are presentable and wear a name badge. If possible, it is recommended to ascertain beforehand the names of the persons who will receive the notification, their relation to the patient, and what they know about the patient’s condition. Other members of the medical team may have met them already and can be a source of background information. Sometimes the family initiated the 911 call and recognized that their loved one had died at that time. On the other hand, a family summoned to the ED may have absolutely no idea that they are about to be informed that their loved one has been critically injured or has died. For this reason, it is useful to have a nurse or colleague advise the family briefly about the general nature of the event and the status of resuscitation as soon as possible. When giving the news, physicians should use clear “dead” or “died” language to be sure that there are no misunderstandings about the outcome being conveyed. Survivors should be assured, if at all possible, that their responses to the emergency were appropriate, that the medical care team did all that was possible, and that the victim did not experience unnecessary discomfort. Appreciation of their presence in the ED, or even in the resuscitation room, also is important to emphasize.

Phone Notification

If the first contact with survivors of an ED death is by telephone, it is recommended that the survivor be told to come to the ED if at all possible. Although family members may ask or even demand to know if death has occurred, allowing some time for assimilation of news by delaying information about the final outcome may be more helpful for the grieving process. Nonphysician staff are particularly useful to summon survivors and can inform the relative that the patient has been involved in an accident or is seriously ill and that things are not going well.

When the notification is to somebody who is more than an hour away or otherwise unable to physically come to the ED to receive the bad news, it must be given by phone. The physician should (1) make sure that the relative has someone present in the room if possible, (2) ask the relative to be seated, and (3) name the person involved. It is best to start with brief information about the circumstances and provide a warning that bad news is coming before breaking it to them. Even a few seconds of preparation in these circumstances can serve to partially attenuate the acute psychic pain. As indicated by the perceived response, the physician may need to ask, “Are you able to talk for a few minutes?” Some individuals may be unwilling or unable to continue after they hear the initial news, and they should be given an “out,” but a definite time to reconnect must be established (e.g., 10 to 15 minutes).

Long-distance loved ones cannot view the body to facilitate confirmation and acceptance and inevitably have questions not addressed in the initial conversation. The relative should be given a telephone contact of someone who actually provided care for the patient. Otherwise, if a relative calls back, a lack of information about what transpired on another shift may cause frustration or even feed the person’s denial or false hope that this tragedy has not happened.

Viewing the Body

At some time immediately after death, an opportunity to view the body should be offered to the family. This may be the first exposure to the body for the survivors and can make concrete what has up to now been only abstract and unreal. Although a majority of survivors find viewing the body helpful, no attempt should be made to force this procedure on survivors, and they should not be made to feel that it is wrong not to view the body. If viewing is presented as an alternative and an aid in the mourning process, it is usually considered helpful.

If possible, the body should be moved to a small room, preferably away from the main treatment area. This not only ensures privacy but also makes the family feel more at ease. Family members should be warned of what to expect, such as color and temperature changes, injuries or invasive premortem procedures, and the presence of endotracheal and intravenous tubing. With sufficient preparation, most people are not shocked by the deceased person’s appearance.

A staff member should remain in the room or within close range at all times. This contact allows the staff to help make the viewing an important and supportive aspect of the grieving process. At times, it may be necessary to touch the body to assure the family that this is appropriate. Survivors should be allowed to remain with the body for as long as seems appropriate. When gross disfigurement has occurred, the viewers should be warned about this, and the body should be discreetly covered where necessary. Survivors may even find that helping to clean and prepare the body (particularly with a pediatric death), holding a loved one, or preparing for transport may allow a final expression of caring.

Family Presence during Resuscitation

It is increasingly common to invite a close family member to attend resuscitation attempts. Offering this option has been endorsed in the 2005 AHA Emergency Cardiac Care guide-
lines\textsuperscript{30} and by the EPEC curriculum.\textsuperscript{1} Emerging evidence suggests that presence during procedures and resuscitations may be beneficial to surviving patients and family members who choose to stay. Less consensus exists among providers, and they often express discomfort with the concept.\textsuperscript{34} If resuscitation is to be witnessed by a family member, a staff member who is dedicated to supporting that person should always be present.

**Sedation for Survivors**

Requests for tranquilizers, sedatives, sleeping medications, or just “something for the nerves” are common. The grieving process is important and difficult work. Prescriptions for a light sedative for a few days may be appropriate but usually require direct evaluation of the survivor by the physician. The survivor needs to know that the psychic pain is to be expected and where to turn for help and support during this difficult time.\textsuperscript{2}

**Autopsy and Closure**

The “event” of death notification should be concluded with a physician expression of condolences and concern for the survivors—all physicians can honestly express the wish that they did not need to be the bearer of such life-changing news.\textsuperscript{33} In many hospitals, chaplains or social workers or nurses are trained in informing the family about arrangements for the body, including notification of a mortician and interface with a coroner, which is not uncommon in ED deaths. If the ED practitioner desires an autopsy, this is an appropriate time to request permission. Autopsies not only are valuable in contributing to the advancement of knowledge, education, quality assurance, and public education but also can be indispensable in minimizing guilt and blame associated with the death of a loved one. Additionally, findings of unknown pathology may be important for family members if there is a genetic factor.

**Consent for Procedures on the Newly Dead**

The use of the newly dead to teach procedural skills is currently being debated in the medical community. It is important to educate residents in procedural skills, and emergency physicians often need to review procedures that they perform very rarely. The newly dead have been a silent source of learning in the past. Although some evidence indicates that the public generally supports the practice, serious questions about respect for bodies and the need for informed consent also have been raised.\textsuperscript{35} The American Medical Association recently published a policy affirming that consent should be obtained from survivors.\textsuperscript{36} In emergency medicine, it has been argued that obtaining consent is not feasible: Finding authorizing survivors is difficult, voluntary consent is questionable in a stressful situation of sudden death, and time pressures require early resumption of other ED activities. Some authorities have tried to distinguish between invasive or major procedures (e.g., thoracotomy, peritoneal lavage, venous cutdown) and minor or less invasive ones, such as intubation. The current ACEP position is that informed consent must be obtained from relatives before any procedures are performed on the newly dead. The performance of involuntary, nontherapeutic invasive procedures, including those performed during CPR, should be regarded as an ethically unacceptable departure from a standard of care that emphasizes the centrality of respect for the patient, the patient’s well-being, and the requirement for informed consent.\textsuperscript{36–38}

**Grieving and Bereavement**

*Grief* is defined as emotional pain induced by sorrow and loss. It is associated with a constellation of symptoms and behaviors that are influenced by cultural and personal issues, other current life stressors, and the relationship of the survivor to the deceased. Survivors are often the “patients” toward whom the emergency physician needs to direct his or her best expertise in the case of an ED death. Giving bad news and sharing in the beginnings of the grief response are among the most difficult situations physicians need to handle. Patients and loved ones also experience grief responses when a sudden medical crisis brings a patient to the ED and is seen as a threat to life and wellness. *Bereavement* is the situation of having experienced the death of a significant person in a survivor’s life.\textsuperscript{39} It is important to understand the range of what can be expected acutely, and to be able to identify those survivors at risk for complicated grief. Recognition of survivors at higher risk for complicated grief may help stimulate referral and decrease the risk of development of major depression and other stress disorders.\textsuperscript{42}

The initial response to any death, whether expected or unexpected, is acute psychic pain that is associated with shock, disbelief, numbness, and inability to process further information.\textsuperscript{2} Some persons display anger, loud screaming, crying, and occasionally acute anxiety or syncope. Alternatively, the physician may observe a false calm or no reaction. In addition to the initial emotional shock, other, more cognitive reactions, including denial, guilt, sadness, fear, shame, and anger, may be exhibited. Reactions may be based on the cultural and personal backgrounds of the survivors. This wide range of expressions is normal and expected; there is no “right” way to grieve. In the ED, outward reactions will in many instances be perceived as problematic and disruptive. The goal of the emergency physician is to help as much as survivors allow and to avoid taking personally the survivors’ anger, resentment, and other outward emotional expressions, even if directed at ED staff.\textsuperscript{2} Likewise, it is important to accept that some survivors will leave the ED still in denial and not emoting; they may need and want to postpone their grieving for what they feel is a more appropriate setting.

A variety of delayed emotional and physical symptoms can emerge as the survivor assimilates the reality that death has occurred. Physical symptoms include fatigue, anorexia, palpitations, hyperventilation, restlessness, headache, irritability, and insomnia. Emotional symptoms, in addition to guilt, anger, depression, and denial, include difficulty in concentrating, lack of organization, fear, and preoccupation with the deceased. These grief responses are to be expected. Special memories can trigger the grief response after the initial grieving period, and the memory and emotional pain of the loss may last a lifetime. Symptoms of grief, including psychic pain, numbness, intrusive thoughts, and disorganization, continue to occur during the recovery of most survivors, gradually becoming attenuated but recurring over months or years without clear “stages.”\textsuperscript{39,40}

Risk factors for difficulty navigating the work of grieving can sometimes be recognized, even in the ED. Such factors include death of a child or long-term spouse, social isolation of the survivor, and a very dependent or conflicted relationship with the deceased.\textsuperscript{2} The physician may be able to alert the survivors’ primary physician or support staff, or even the at-risk survivor directly, that ongoing work will be required to see this grief to resolution.

**Grief Reactions in Staff**

The impact of death in emergency medicine is significant for the staff, including physicians. Stressors that exacerbate grief and the emotional impact of ED work include exposure to premature deaths of young people or to the injuries of victims of random and senseless violence, care for those who may have
caused an accident or injury, and care that must be delivered rapidly on the basis of scant knowledge, but which other professionals can later second-guess. The ED clinician also carries a personal history that may include circumstances that make particular emergencies hit a raw nerve of which colleagues may not be aware, as, for instance, an alcoholic parent, a sibling who committed suicide, or a friend killed by a drunk driver.

Because of the sometimes overwhelming contact with death and dying in the ED, it is important to have intradepartmental mechanisms in place for helping address staff grief responses. At morbidity and mortality conferences, some discussion should be allotted to ethical, sociologic, and emotional sequelae of the cases being presented. The morbidity and mortality analysis process itself helps “make sense” of difficult situations and is part of the grieving process for health care practitioners. Case conferences, including a full range of medical personnel, chaplains, and social workers, are useful to articulate and share sadness, anger toward patients, and other emotional and cognitive work required for healing. This is particularly important to offer staff after major community disasters. Although for some people denial is a positive coping mechanism, for others the opportunity to share and express emotions is needed to begin to move forward and resume the work of caring for patients.

Palliative Care in the Emergency Department

Providing quality palliative end-of-life care is important in the ED. Education in Palliative and End-of-Life Care for Emergency Medicine (EPEC-EM) is a curriculum specifically designed to provide emergency clinicians with the information and skills to practice ED-based palliative care.1 The evidence that we do not know what others want for themselves or family members at the time of critical illness is discussed in the first part of this chapter. In the case of a cardiopulmonary arrest or major trauma resuscitation, attempts at curative intervention are always indicated unless the emergency physician has clear instructions from the patient or surrogate to the contrary. In less critical situations, however, guidance about the goals and direction of ED care is needed, and management strategies should be “patient-centered.”1 Although some would argue that it is time-consuming and unnecessary for emergency physicians to develop a nuanced approach to end-of-life care, it is no longer appropriate to provide all patients with maximal medical treatment and to “let the admitting doctors sort out the other issues.” Comfort and optimal quality of life become a higher priority for many patients with severe chronic diseases, such as cancer, COPD, heart failure, renal insufficiency, or dementia. Some of the procedures that are normal interventions in emergency care may not be appropriate in this subset of patients.

Establishing Goals of Care

The primary skill that emergency physicians must have in managing patients near the end of life is the ability to communicate. In a true emergency, such conversations must take a back seat to resuscitation interventions. In many patients, however, it is not imperative to treat before discussion or diagnosis. In the ED setting, several useful methods can be to establish what treatments patients want near the end of life.

Reviewing and Honoring Advance Directives

Written advance directives can help guide treatment decisions in the ED as well as on hospital admission. Although such documents often do not foresee the particular medical emergency that precipitates an ED visit, their existence indicates that a patient has considered how medical care should or should not look. Advance directives may indicate that aggressive lifesaving interventions are desired, or that a patient is in the dying process and wants to be kept comfortable. People’s wishes change over time, and written advance directive requests should be reconfirmed at the time of an acute crisis. The emergency physician should be well versed in the technicalities of the various forms of written legal advance directives that exist.

Processing Verbal Requests

Verbal requests to titrate or limit procedures can be made by the patient or the patient’s surrogate. The emergency physician should determine whether the patient has decision-making capacity and, if such capacity is lacking, who will be the spokesperson for the patient. Invasive tests and procedures may not be performed on patients without their consent. In emergency situations, physicians rely on the “emergency exception” to informed consent and act to preserve life, or at least to buy time to consider options. Many situations in the ED, however, do not require immediate intervention, or they allow for a less invasive alternative (such as mask ventilation for respiratory failure) while the patient’s goals are discussed.

Initiating a Conversation on Goals of Care

Emergency physicians see many sick patients who do not have written advance directives but are temporarily stable enough to have meaningful conversations about their needs and goals, their perception of where they are in the course of their disease, whether they wish to cure an intercurrent problem, which symptoms require management, and how much effort they wish to have undertaken if resuscitation is needed to preserve their life. Patients with seemingly lethal conditions may be aggressively pursuing curative or at least disease-modifying options, whereas the heavy burden of suffering other patients are experiencing may not be obvious until they are asked specifically about their illness. The only way to determine the patient’s needs is to ask.

Questions that can be useful for initiating this conversation are listed in Table 201-1. Pulling up a chair, sitting with the patient and family, and spending a few minutes clarifying the patient’s values and view of the present and of the future may make a big difference in designing the patient’s care and disposition.

It is useful to start the “goals of care” conversation with a global understanding of the patient’s illness, values, fears, and expectations. This makes the “procedures” part of the conversation flow naturally. The physician can then suggest to the patient and family what treatments will be useful (or not) in the context of overall goals and values. Antibiotics may be appropriate for an acute pneumonia, but they may not be indicated in a patient with advanced dementia who has been bedridden and unable to communicate for several years. Intubation will be acceptable to some patients with COPD, whereas others who have struggled on the ventilator before may not wish to experience that discomfort again. Intravenous hydration is useful to correct dehydration but may merely increase secretions in the patient who is actively dying. All of these interventions need to be considered in the context of caring for the patient and enabling them to achieve their goals.

Initiating Advance Directives and DNAR Orders

Several authors have suggested that the ED may be an important link in initiating advance directives because it often is the
Treating Symptoms Requiring Palliation

When a patient is suffering from a disease that is not curable, he or she may still want a variety of medical interventions as part of care: antibiotics for intercurrent infections, drainage of effusions that cause shortness of breath, wound care for decubitus ulcers, decompression of bowel obstructions, and aggressive pain management. On the other hand, the best way of maximizing patient function and quality of remaining life may require de-emphasizing diagnosis and primarily addressing symptoms. The most common reason that patients with end-stage illness seek emergency care is for control of intolerable symptoms such as nausea, vomiting, dyspnea, severe constipation or diarrhea, and pain (Box 201-3).

The emergency physician may encounter several unfamiliar concepts when attempting to treat symptoms in frail persons near the end of life. One of the more “foreign” concepts to most emergency physicians is the treatment of symptoms without diagnosing the underlying cause, even though this often is the appropriate option. Additionally, concerns regarding “drugging” patients or overtreating them, although common, are mostly unwarranted. Nevertheless, worry about unintended consequences may lead to underdosing medica-

Patient’s portal of access to the hospital.41 Wrenn and Brody described a small series of patients for whom the emergency physician wrote DNAR orders on admission.62 Balentine and colleagues described another series in which few negative responses were obtained from the families who were approached.63 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5 Both papers point out that fragmentation in responses were obtained from the families who were approached.5
signs or outward expressions of discomfort commonly observed with acute pain. Patients with advanced illness and pain may be tolerant to opioids and require high doses to reach comfort. This inevitably causes discomfort on the part of the provider. Patients suffering from malignant pain may need continuous infusions of opioids to obtain relief. These concepts are reviewed in the EPEC curriculum, and many other resources for learning about dosing of analgesics in these situations are available.1,6

When available, palliative care consultation should be sought for treatment of malignant pain. However, pain and palliative care consultation is not uniformly available, particularly during the evening and night hours. Therefore, emergency physicians must have the basic knowledge to treat severe pain. Rapid opioid dose escalation is the most important principle in patients with cancer on opioids. Doubling of the dose may be required until successful analgesia is reached.65 Understanding dosing is key as well. With intravenous administration of morphine, serum levels will be maximal in 6 minutes, which translates to the need to rapidly reassess and redose if the patient is in severe pain. Providing analgesic stability is important, and this is done by providing a long-acting formulation (e.g., MS Contin), with an immediate-release short-acting agent for breakthrough pain. Side effects from opioids must be anticipated as well. Rising serum levels of opioids stimulate the chemotactic trigger zone, causing nausea. Educating the patient that nausea will subside within days is helpful. Minimizing fluctuations by using long-acting agents whenever possible can limit this form of nausea. Constipation is a common effect of opioids, and tolerance will not develop to this very frustrating complication of narcotics. Prevention is far easier than treatment, and a stimulant laxative should be part of all narcotic prescriptions for malignant pain. The use of nonsteroidal anti-inflammatory drugs may be helpful in potentiating the effects of opiates in cancer patients. Recognizing neuropathic pain also is important, because medications such as gabapentin may be added. It is important to clearly explain the proposed treatment plan to the patient and caregivers, to monitor the response to treatment and side effects, and to coordinate changes in treatment regimens with the primary care physician.1,6

Nausea and Vomiting

Nausea and vomiting arise from triggers in the gastrointestinal tract, cerebral cortex, vestibular apparatus, or the chemoreceptor trigger zone in the fourth ventricle. The neurotransmitters involved include serotonin, dopamine, acetylcholine, and histamine. Successful treatment of nausea and vomiting involves selecting the drugs that will target the right receptors. In addition to usual antiemetics, dexamethasone, ondansetron (which reduces secretions and may be useful in cases of intestinal obstruction), and tetrahydrocannabinol may be important adjuncts for the control of nausea.1,6

Constipation

Constipation is multifactorial near the end of life; causes include decreased mobility, medications, mechanical obstruction, and dehydration. Stimulant laxatives and then osmotic laxatives should be tried in escalating doses, and combinations may be needed. Opioid-related constipation can be a major problem; tolerance does not develop to this side effect of chronic and high-dose use. Every attempt should be made to prevent rather than treat constipation by anticipating the need for stimulant softener combinations when opioids must be used chronically. In cases of mechanical small bowel obstruction, medical management with clear liquids, loper-

amide, and octreotide results in resolution in a majority of patients.1,6

Anorexia and Cachexia

Anorexia and cachexia develop in patients with advanced diseases and may be more stressful for the family than for the patient. Parenteral nutrition does not necessarily reverse these processes, nor do they affect life expectancy, although infections of the esophagus should be considered. Appetite stimulants are sometimes useful.6

Shortness of Breath

Shortness of breath also can be part of the last stages of airway disease or cancer involving the lungs. There are many causes, and several treatments may be helpful. Options include symptomatic treatment with oxygen (which may not work if central triggers are operating), anxiolytics, and low-dose opioids, which may decrease the sensation of breathlessness. Malignant effusions may require drainage. In the actively dying patient, morphine and atropine can be used to dry secretions, slow breathing rates, and decrease the work of breathing.6

Depression

Psychosocial distress is exceedingly common in patients suffering with incurable illness. Anxiety and depression have been found to have a negative impact on survival and to decrease quality of life. These issues are best addressed by the primary care provider. Emergency providers can provide empathy and support and recognize that these symptoms are not inevitable components of the dying process and therefore deserve attention.

Special Situations and Diseases

Advanced Dementia

Alzheimer’s dementia is a prolonged and relentless chronic disease with a course that can extend up to 20 years. With severe dementia, patients may be combative, incontinent, and unable to ambulate. In the terminal phases of the disease, they are bedridden, mute, and dysphagia and suffer from intercurrent infections.67 In the demented patient, invasive procedures often require restraints and sedation, and the emotional burden to the patient is high. Even hospitalization, administration of intravenous fluids or antibiotics, and other common interventions are frightening to patients with dementia. As an example, percutaneous gastrostomy or feeding tubes do not prolong life in these patients, and their qualititative benefits are questionable. They do not prevent aspiration, provide palliation, or improve function in a progressive severe disease like dementia.56,85 For the emergency physician, the increased burden in combination with decreased benefit, even of the simplest procedures such as administration of antibiotics, means that interventions should be thoughtfully chosen and discussed beforehand with surrogates when there is time to do so. Addressing concerns of caregivers also is particularly important in dealing with families of patients with dementia. Depression is common in caregivers; the burden of caring for patients is very heavy, and grieving may occur before death as the person that they knew disappears in front of them.

Renal Failure

Dialysis has been a technical success in prolonging life for patients without kidney function. Because it is now so common,
physicians do not realize that the annual mortality rate is greater than 25% for patients with significant comorbid illness. Understanding that dialysis is a choice and not a mandatory intervention may be a useful attitude to affirm in discussing long-term choices with patients and their families in the ED. In the patient with dementia or cancer, electing not to treat renal failure is an option that should be offered to patients and families.

Heart Failure and Chronic Obstructive Pulmonary Disease

Although the physiologic parameters of terminal heart failure and COPD are well described, death from these diseases is commonly unexpected and may occur as part of a sudden acute deterioration that is not remediable. As a consequence of the entry-reentry pattern of dying associated with CHF and COPD, many patients will not receive good palliative care until the last days of life. However, some guidelines are available to assist the provider in determining prognosis. When death occurs, it is important to remind the survivors that the underlying disease is the real cause of mortality.

On the other hand, if the patient presenting with acute decompensation becomes stabilized, the emergency physician may be the best person to have a conversation concerning advance planning with the patient and family to establish what kind of resuscitation measures should be performed if the patient suffers a cardiac or respiratory event in the hospital and who should make decisions on behalf of the patient if he or she should become incapacitated at some time during the admission. In patients with many types of chronic diseases of the entry-reentry type (see Fig. 201-1), the period after an emergency has resolved (at least temporarily) often is the best time to establish what interventions would be appropriate if decompensation occurs again. In terminal stages, an undue focus on diagnostics is more common in these patients than in patients with cancer, particularly if the lethality of these conditions is not acknowledged. Palliative care or hospice referral often is useful in assisting the patient with understanding and acknowledging prognosis and establishing intentional and realistic projects and goals for their remaining life.

**KEY CONCEPTS**

- In emergency medicine, it is essential to act rapidly, with the presumption of curative goals, and it often is impossible to withhold initial interventions.
- Advance directives and patient wishes should be honored whenever possible, including withdrawal of invasive support if the patient’s desire to not receive such treatments is determined after initial ED intervention.
- Suffering is not the same as physical pain: The body experiences pain, whereas persons experience suffering, particularly when physical changes threaten their future.
- Patients have individual perceptions of burdens and benefits when they live with chronic illnesses. The only way to understand a person’s quality of life and whether treatment is “right” for a patient is to have a conversation.
- An important aspect of the initial ED evaluation of a patient with a life-limiting illness is to ascertain the patient’s general wishes regarding resuscitation and related issues. The conversation with family and patient can begin by asking the following questions: “What kind of resuscitation do you wish to receive if an emergency occurs after admission?” “Whom do you want to make decisions for you if you cannot?”
- A discussion of goals of care is more effective if it starts by clarifying the patient’s broad values and goals. From the broad discussion, the clinician can suggest what procedures may or may not be useful in attaining the patient’s goals.
- The purposes of hospitalization for persons with severe terminal diseases should be clear and in line with the patient’s values.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Practicing good medicine in the emergency department (ED) may have been enough to avoid legal entanglements historically, but no longer. Federal and state laws now directly govern the practice of emergency medicine. The magnitude and complexity of the controlling legal authority, plus the significant penalties for noncompliance such as criminal sanctions, civil lawsuits, civil monetary penalties, or exclusion from participation in Medicare and Medicaid, dictate that emergency physicians acquire functional knowledge of these laws.

Federal law, the Emergency Medical Treatment and Active Labor Act (EMTALA), (a section of the Consolidated Omnibus Budget Reconciliation Act of 1985 [COBRA]), also known as the “antidumping” statute, governs how emergency physicians must triage, register, examine, provide workup, treat or stabilize, discharge or transfer, utilize hospital resources, and involve medical staff expertise when caring for patients presenting to the ED.1-3 State laws further control the practice of emergency medicine through such issues as consent, reporting requirements, confidentiality requirements, forensic and police matters, civil commitments, and emergency medical services (EMS) statutes.

EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT

EMTALA originally was enacted to prevent private hospitals from transferring (“dumping”) medically unstable, indigent patients to public hospitals. Subsequent amendments to the law, government regulations, and court decisions greatly expanded the reach of EMTALA, such that the law now sets national standards of care for emergency services.2-4 Today’s practice of emergency medicine requires a firm understanding of EMTALA’s statutory requirements and how the regulatory agencies and the courts interpret the three main aspects of the law: screening, stabilizing, and discharging or transferring ED patients.

Medical Screening Examination

Any person who comes to an ED requesting examination or treatment must be provided with an appropriate medical screening examination (MSE).5 The purpose of the MSE is to determine whether the patient has an emergency medical condition (EMC).6,7

Emergency Medical Condition

The EMTALA defines an EMC as “acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in any of the following: (1) placing the health of the individual (or, with respect to a pregnant woman, the health of the woman or her unborn child) in serious jeopardy, (2) serious impairment to bodily functions, or (3) serious dysfunction of any bodily organ or part.”6 In the case of a pregnant woman who is having contractions, an EMC is defined as one in which “[t]here is inadequate time to effect a safe transfer to another hospital before delivery, or the transfer may pose a threat to the health or safety of the woman or the unborn child.”7

Competent physicians can reasonably disagree whether certain conditions are serious enough to constitute an “emergency.” However, the courts hold that the relevant factor is whether the physician perceived the patient to have an EMC, not whether the patient actually had an EMC, and not whether the emergency physician or hospital should have known that the EMC existed. The focus is whether the physician or the hospital in fact actually determines that the patient has an EMC; the standard is subjective, not objective.8 If the physician and the hospital perform an appropriate MSE and in good faith determine that no EMC exists, the courts will not retrospectively review that decision; rather, it will be a simple state malpractice issue of whether the examination and diagnosis met the applicable standard of care.

If the MSE does not reveal an EMC, further care of that patient is not controlled by EMTALA, so the law’s provisions governing stabilizing treatment, transfer of the patient, or involvement of on-call physicians no longer apply. This interpretation emphasizes the critical importance of documentation of the presence or absence of an EMC during a patient’s initial ED evaluation. A checkbox to indicate such should be on every ED medical record.

“Any Individual”

Everyone who presents to the ED requesting care must be screened. Whether the patient is indigent, a member of a managed care plan, or covered by Medicare, Medicaid, or private insurance is irrelevant; the hospital must provide everyone who presents for care with an MSE.5 This includes all patient populations, such as illegal aliens, minors, and
private patients of the hospital's medical staff but excludes persons who are already patients of the hospital, such as inpatients or outpatients undergoing a scheduled procedure at the hospital who are brought to the ED for emergency care. The screening of minors is discussed later in the section on consent.

Private Patients

In many hospitals, members of the hospital’s medical staff often meet their private patients in the ED. These patients are examined and treated by their private physicians, not the emergency physician on duty. Such practice is entirely appropriate to maintain physician-patient relationships and is allowable under EMTALA. However, the hospital should have prearranged procedures for handling private patients that do not unduly delay the patient’s MSE; otherwise, the hospital could be liable under EMTALA for failure to provide an “appropriate” MSE. Delay of treatment in such instances also frequently results in hospital liability through state malpractice actions.

All private patients should be triaged according to the hospital’s established protocols. If the triage nurse determines that the patient requires immediate care, the emergency physician on duty should provide the necessary treatment until the patient’s private physician arrives in the ED to assume the patient’s care.

If triage determines that the patient does not require immediate care, the emergency physician should see the patient in the order consistent with the usual practice of the ED, generally in the order of acuity or time of arrival. If the private physician comes to the ED and sees the patient before the emergency physician does, the examination by the private physician constitutes the required MSE by the hospital. In this situation, no undue delay of the MSE for any nonmedical reason has occurred. However, if the patient’s private physician has not arrived by the time the emergency physician would normally examine the patient, the emergency physician should perform an MSE. If no EMC is evident, the patient can wait for his or her physician to arrive. If an EMC exists, the emergency physician should undertake appropriate stabilizing treatment until the patient’s physician arrives.

“Comes to the Emergency Department”

The Centers for Medicare and Medicaid Services (CMS) (formerly the Health Care Financing Administration [HCFA]) deems anyone on hospital property to have “come to the emergency department.” According to CMS, “hospital property” consists of the entire main hospital campus, including parking lots, sidewalks, and driveways, and any ambulance owned and operated by the hospital, even if the ambulance is not on hospital grounds. CMS then divides hospital property owned and operated by the hospital, even if the ambulance is parking lots, sidewalks, and driveways, and any ambulance could be liable under EMTALA for failure to provide an “appropriate” MSE. Delay of treatment in such instances also frequently results in hospital liability through state malpractice actions.

Presentations to the hospital’s dedicated ED require only a request for examination or treatment of a medical condition; it is not required that the presentation be for a medical condition that constitutes a true emergency to trigger EMTALA’s screening duty. Presentations to hospital property other than the dedicated ED do, however, require the request to be for an EMC before EMTALA applies.

“Parking” of Patients Brought by Emergency Medical Services to the ED

Overcrowding led some hospitals to ignore ambulance patients and leave EMS to care for them until the hospital “accepted” the patient, a practice termed “EMS parking.” These hospitals erroneously believed that unless they accepted responsibility for the patient, they had no EMTALA duty to provide care or accommodate that patient. CMS issued a memorandum reminding hospitals that their EMTALA obligation begins the moment the patient “comes to the ED” and a request is made on behalf of the patient for examination or treatment of a medical condition, not when the hospital “accepts” the patient. (Of note, the practice of “parking” EMS patients also may violate Medicare regulations, which require hospitals to “meet the emergency needs of patients in accordance with acceptable standards of practice.”)

Subsequently, EMS organizations cited the CMS memo as requiring hospitals to take instant custody and responsibility of all patients brought in by EMS. In response, CMS issued a clarification to its “parking” memo, stating that its guidance “should not be interpreted to mean that a hospital cannot ever ask EMS personnel to stay with the person they transported to the ED when the hospital does not have the capacity or capability to immediately assume full responsibility for the individual.” Also pointed out was that in certain circumstances, such as an influx of multiple trauma victims, it would be reasonable for the hospital to ask the EMS provider to stay with the patient until such time as the ED staff became available to care for that person.

CMS did note, however, that “even if a hospital cannot immediately provide an MSE, it must still triage the individual’s condition immediately upon arrival to ensure that an emergent intervention is not required and that the EMS provider staff can appropriately monitor the individual’s condition.”

CMS will review complaints of this nature on a case-by-case basis to determine if the hospital violated EMTALA’s medical screening mandate.
National Emergencies or Disasters

Under certain circumstances, the Secretary of Health and Human Services can exempt hospitals from EMTALA during times of national or local disasters or terrorist acts, bioterrorist events, or pandemic infectious disease.¹⁹,²⁰

Request for Examination or Treatment of a Medical Condition

Mere presence in the ED or on hospital property is not sufficient to trigger the hospital’s duty to provide an MSE; a request for examination or treatment also is necessary. The request can be made by anyone on behalf of the patient, including EMS personnel, a police officer, or a babysitter; the request does not have to come from the patient, a family member, or a legal guardian.⁵

Also, if a person is unable to speak to request care, that person’s behavior may constitute a request if the hospital’s personnel are aware of the behavior and a prudent layperson would believe that the behavior indicated a need for examination or treatment.⁵

Other Hospital Department Functions

Hospital EDs serve many functions other than the evaluation and treatment of patients with true medical emergencies. Physicians on the hospital staff may use the ED in the off-hour periods to provide injections or obtain laboratory tests or radiographs on their patients. Police use the ED to obtain blood alcohol samples on allegedly intoxicated automobile drivers. Some hospitals may use the ED to provide urine drug screens on injured workers, prescription refills, allergy shots, rabies vaccinations, blood transfusions, or other community medical services such as blood pressure screening or flu shots.

Laboratory Tests and Radiography Requests

The test category includes urine or serum drug screening, routine laboratory tests, and imaging studies. In each case, no immediate medical decision making is required. The patient’s physician determines the indication for the studies and is responsible for the patient’s care, including following up on the test or radiography results. The patient is not requesting “examination or treatment for a medical condition” by the hospital’s ED, so the hospital does not need to provide an MSE.

Such patients should not be sent through triage and should not have their vital signs taken, and the hospital should not create the usual ED chart for them. They should not be asked to sign the usual ED “consent for treatment” forms, which could imply they were requesting examination and treatment. Separate paperwork should be used to document the visit, the particular test performed, the patient’s informed consent for the testing, any communication with the private physician, and a specific statement that the patient is not requesting an MSE from the ED, with the patient’s signature.

Some persons come to the ED on their own, not at the request of their physician, and request a test (e.g., for pregnancy or human immunodeficiency virus serostatus). All such persons should be given an MSE before any test is conducted. If the person declines the MSE, he or she should be referred elsewhere to obtain the requested test: outpatient clinic, personal physician, or public health clinic, or a local drugstore for a pregnancy test. Documentation that the person declined the offered MSE is essential.

Minor Treatments

The minor treatment category includes allergy shots, tetanus shots, rabies vaccines, bloodletting or blood transfusions, chemotherapy infusion for cancer or possible organ transplant rejection, reinsertion of a feeding tube or Foley catheter, prescription refills, suture removals, antibiotic injections, and narcotic injections for chronic pain syndromes. Patients presenting to the ED requesting treatment should be given an MSE. In each instance, the common denominator is the element of medical decision-making.

Antibiotic and narcotic injections require special comment. Physicians, particularly in rural hospitals, send their patients to the ED and then call in phone orders for parenteral medications. The patients are not examined by the emergency physician on duty. This practice should be avoided, and it probably violates EMTALA because the hospital does not provide the patient the same MSE as for any patient with the same complaint. It is irrelevant if the patient’s private physician performed an office examination immediately before sending the patient to the ED. This requirement of EMTALA may not be cost-efficient medicine, but both CMS and the courts agree that the hospital must provide an MSE to any person who comes to the ED and requests examination or treatment for a medical condition.⁵,²¹

All patients presenting for minor treatments should be triaged, registered, and managed as for all other ED patients. The ED evaluation should determine whether the patient’s condition meets the definition of an EMC before the hospital administers any medications. CMS and the courts will assume that these patients requested examination or treatment, and the hospital must demonstrate that either (1) these patients did not request that an MSE be performed or (2) the ED evaluation did not reveal an EMC.

CMS recently attempted to eliminate application of EMTALA to persons coming to the ED for reasons other than seeking emergency care. However, the language of the new regulations really did not change anything. The hospital still must perform an MSE of an extent necessary to determine whether an EMC exists, regardless of whether the patient’s presenting complaint appears to be for a “nonemergency” condition.⁵,¹³

Prescriptions

In small communities, local pharmacies frequently are not open continuously. Hospital pharmacies, sometimes through the hospital ED, fill prescriptions for patients in off-hours. Patients presenting to the ED to fill these prescriptions do not need an MSE. If the prescription is filled through the ED, the hospital should have the patients sign a form indicating they are not requesting an MSE, for the same reasons and in the same manner as when tests are done in the ED at the request of physicians.

This situation is different from that in which patients present to the ED for prescription renewals. Patients requesting “refills” on this basis are seeking not pharmacy services but medical decision-making services from a physician by asking for a prescription renewal to treat an underlying medical condition.⁴¹ Therefore, patients seeking prescription renewals must be provided with an MSE.

Sexual Assault Cases

The ED often assists police in the collection of evidence related to alleged sexual assault cases. If a person comes to the ED solely to provide evidence for the criminal investigation
and is not requesting examination or treatment for a medical condition, no MSE is required. However, if the person complains of pain or injury, or wants pregnancy or sexually transmitted disease prophylaxis, that person is requesting examination or treatment for a medical condition and must be provided with an MSE.2,24

**Preventive Services**

Blood pressure screening and vaccination services do not require an MSE. The patient receiving such services is not requesting examination or treatment for a medical condition. The patient is attempting to prevent illness prophylactically, not seeking treatment of an illness. These vaccinations are distinct from tetanus boosters, because boosters typically are administered in response to injury and represent a component of medical decision-making and treatment.

**Police Blood Alcohol Tests**

For both medical and legal reasons, an MSE should be offered to all persons presenting to the ED for police-requested blood alcohol samples.23 This scenario is different from that in which patients present to the ED to have blood tests done as ordered by their physicians. Persons in police custody have not been examined by a physician, and the results of the test will not be returned to a physician to care for the patient. The police officer brought the patient because of aberrant behavior, suspected to be caused by alcohol intoxication. Many diseases mimic alcohol intoxication, including hypoglycemia, cerebral hypoxia, head injury, metabolic abnormalities, and other toxins. Medically, alcohol intoxication should not automatically be presumed as the cause of the patient’s condition merely because it is so common. The emergency physician should examine the person in custody to determine if an EMC exists.9

The patient may refuse the MSE and request that only the blood be drawn. If the patient appears competent, this can be done. The refusal of the MSE must be documented, as noted for other testing done in the ED, with additional documentation of the risks and benefits of the offered MSE and careful notation of the patient’s competence. If the patient is too intoxicated to make medical decisions, release from the ED should be delayed until the patient is competent enough to make rational decisions. Only physicians should assess and document a patient’s competence; other ED personnel should not be allowed to make these decisions.9

Again, under EMTALA, the “request for examination or treatment” can be made by anyone on behalf of the patient. The police officer’s request for blood alcohol sampling may be sufficient to constitute the request for an MSE.

**Direct Admissions through the Emergency Department**

Direct patient admissions are always problematic. In the three most common scenarios, the patient (1) is sent to the ED after being examined by the primary care physician in the office, (2) is sent in after phone contact with the physician, or (3) is accepted by phone-in transfer from a different hospital ED or inpatient setting. In all three cases, the patient’s physician intends to see the patient after admission to the inpatient setting, rather than in the ED. Medically, each presentation may require a different level of acute intervention, but legally all are the same under EMTALA.2,23 CMS does not apply the law to inpatients regardless of whether they are directly admitted to the floor, directly admitted by way of the ED, or “boarded” in the ED awaiting bed placement. Even if the inpatient is brought down to the ED, the law does not apply.2,24

An inpatient is defined as “an individual who is admitted to a hospital for bed occupancy for purposes of receiving inpatient hospital services...with the expectation that he or she will remain at least overnight.”2 It does not matter if the situation changes later and the patient can be discharged or transferred to another hospital and does not actually use the bed overnight. The key element is that the patient must be formally admitted with a documented admission order. A physician’s intent to admit or a level of acuity indicating that the patient “obviously will be admitted” is not enough to satisfy the definition. Documentation is critical.2,24

CMS does not consider patients admitted to observation status to meet the regulatory definition of admitted patients (not admitted for purposes of receiving inpatient services), so EMTALA still applies to the care of observation patients, such as patients managed in ED chest pain units.2,24 Therefore, under existing regulations, persons who were directly admitted and sent through or held in the ED from a physician’s office, a nursing home, or in transfer from another ED or another hospital inpatient setting are no longer covered by EMTALA, even though they have “come to the hospital’s emergency department.”

**Health Care Providers Qualified to Do the Medical Screening Examination**

EMTALA does not specify whether a physician, a nurse, or another health care provider must perform the MSE. CMS regulations require that the screening examination be done by “qualified medical personnel,”24 and that the hospital’s governing body formally designate, in writing, who is a qualified person to perform medical screening on behalf of the hospital.15,26 CMS specifies that the hospital cannot allow the medical director of its ED to designate who is qualified to perform screenings on behalf of the hospital.27

Triage by a nurse is not considered to constitute an MSE. Neither CMS nor the courts accept triage as adequate to determine whether an EMC exists.29

It is strongly recommended that hospitals designate physicians to be primarily responsible for MSEs performed in the ED. Either the physician personally performs the screening or is directly responsible for examinations performed by physician assistants or house staff. It is appropriate to use physician assistants and nurse practitioners to screen patients who are determined by nurse triage to have less acute or severe conditions. However, the physician on duty should have a direct supervisory role with the physician assistant and a collaborative arrangement with a nurse practitioner—the difference being that nurse practitioners have an independent state license, whereas the physician assistant functions under the license of the physician.

**Ancillary Services as Part of the Medical Screening Exam**

The law requires hospitals to provide the screening examination “within the capabilities of the hospital’s emergency department, including ancillary services routinely available to the emergency department.”9,5 According to CMS, this means that the scope of an MSE may “range from a simple process involving only a brief history and physical examination to a complex process that also involves performing ancillary studies and procedures such as (but not limited to) lumbar punctures, clinical laboratory tests, computed tomography scans, diagnostic tests and procedures.”9,26
Because the stated purpose of the MSE is to determine whether an EMC exists, CMS and the federal courts hold that the hospital must conduct whatever examination is necessary to make that determination. It may take only a visual glance to rule out any EMC in a patient with a rash. However, if it takes a complete neurologic examination, computed tomography, and lumbar puncture to decide whether that patient has a serious underlying infection, then those procedures are considered part of the MSE.

Thus, if the ED usually has ultrasonography, computed tomography, ventilation-perfusion scans, and similar tests available, it must use those resources if necessary to determine whether the patient has an EMC. However, the hospital is obligated only to utilize the resources ordinarily available to its ED. Neither the statute nor the regulations mandate that hospitals expand resources or offer additional services to ED patients. An exception may be the use of interpreters for patients not fluent in the English language, which is required by the Medicare conditions of participation.

CMS views the ancillary services available to the ED as including the services of on-call physicians if their expertise is required to decide if the patient has an EMC. If the emergency physician cannot determine whether a patient has an EMC, the physician must use the on-call physician services to help make that determination. For example, if it takes an on-call surgeon to decide whether a patient has an “acute abdomen,” the surgical evaluation becomes an integral part of the hospital’s MSE.

**Policies, Procedures, and Practice Guidelines**

The federal courts hold that an appropriate MSE has two components: (1) the examination must be “reasonably calculated to identify critical medical conditions,” and (2) the “exact same level of screening must be uniformly provided to all patients who present with substantially similar complaints.” In other words, a hospital satisfies the requirements of EMTALA if it conducts standard screening procedures, uniformly, to all patients with similar complaints and circumstances.

Each hospital determines its own standard screening policies and procedures. By necessity, each hospital’s standard will be individualized, because each hospital ED has its own capabilities and different ancillary services available. Once a hospital defines its standard screening process, however, it must apply that process uniformly to all patients presenting with similar complaints, and material departure from its standard screening procedure constitutes inappropriate screening under EMTALA. Because motive is not a relevant issue in the federal courts (except the 6th Circuit Court) or during CMS investigations, liability may result from any material deviation of the hospital’s screening process, regardless of the hospital’s motive and regardless of the reason for the deviation. For example, a Florida hospital’s screening policy stated that triage would be conducted within 3 minutes after a patient’s arrival at the ED. In one instance, a patient was not triaged until 45 minutes after arrival; this delay constituted a violation of the law because the hospital did not follow its own policy.

Once hospitals define their own standard screening process, they will be held to that standard, by both plaintiffs and the government enforcers. Investigators and plaintiff attorneys will subpoena and closely examine the hospital’s policies and procedures, medical staff bylaws, ED rules and regulations, practice guidelines, and other written information on the screening process. They will compare the written process to what actually transpired. These hospital documents must be drafted very carefully to avoid unintended liability.

Practice guidelines or protocols, including managed care manuals, adopted by EDs or hospitals may be treated essentially the same as the hospital’s own policies and procedures. They are also routinely used to demonstrate that the hospital “failed to follow its own rules” when hospitals and physicians do not adhere to their adopted parameters. In fact, practice guidelines are used against physicians and hospitals much more frequently than they are used to their benefit in malpractice litigation.

**Registration Process, Collections or Insurance Information, and Authorization**

CMS does allow hospitals to conduct reasonable registration procedures in the ED, including collecting insurance data or cash at the time of registration, as long as the process does not delay the MSE. A reasonable registration process may include obtaining demographic data, the name of the patient’s physician, and determining whether the patient is insured and the type of insurance. During the registration process, the patient can sign the hospital’s usual “informed consent to be examined” form and a routine form that holds the patient financially accountable for any charges not covered by the patient’s insurance carrier.

The key is to create parallel tracks for medical and financial issues and to ensure that the financial track never interferes with the medical care in any way. “Bedside registration” probably is necessary under the existing regulatory scheme to avoid “no-delay” violations, because CMS would consider any delay in access to the MSE due to diversion to the registration area to be against the law. Waiting for examination and treatment because the ED is overwhelmed is not a violation, but waiting for examination because the registration clerks are collecting insurance information may be.

CMS warns hospitals not to coerce patients into leaving before they receive their federally guaranteed MSE, stating “reasonable registration processes may not unduly discourage individuals from remaining for further examination.”

Collection of copayments, down payments, advanced beneficiary notifications (ABNs), or signatures on managed care financial forms may constitute such “economic coercion” if not done very carefully. Hospitals also must ensure that staff behavior does not create a hostile environment or constructive denial of the MSE.

Furthermore, hospitals should never delay a patient’s MSE in order to obtain prior authorization from a managed care organization (MCO). First, managed care authorization is authorization for payment only—it is not authorization for treatment; and second, CMS explicitly bans prior authorization for managed care plans before completion of the MSE and commencement of stabilizing treatment. Hospitals may obtain authorization for payment from insurance entities only “concurrently” with stabilization of the patient. Hospitals are legally obligated to provide the MSE, and they will be held to that standard regardless of the financial pressures placed on them by MCOs. As a related issue, “[m]anaged healthcare plans cannot deny a hospital permission to examine or treat their enrollees. They may only state what they will and will not pay for, and regardless of whether a hospital is to be reimbursed for the treatment, it is obligated to provide the services specified in EMTALA.”

Patients often ask questions about their obligation to pay for emergency services, particularly whether their insurance will cover the visit or how much it will cost to receive care at the ED. Regarding EMTALA, all patient questions should be answered forthrightly, honestly, and completely by the hospital staff. Generally, routine financial questions can be answered...
by registration personnel or triage nurses trained to give “stock answers,” to not discourage or coerce the patient in any way, and to encourage the patient to stay, with discussions of payment deferred until after an MSE is performed.

After the hospital answers the patient’s questions, the patient is responsible for making informed decisions about further aspects of care. If a patient chooses to withdraw a request for examination or treatment and leave the ED, hospitals must carefully handle the interaction related to the patient’s “voluntary withdrawal” (see the later section on consent). Whenever the patient intends to leave, the staff should involve the physician on duty.

Regardless of managed care status, “VIP” status, private patient status, or any other classification, all patients should be processed in the same manner. Additionally, the triage team, physician and nursing staff, and all clinical personnel should not know the patient’s insurance status throughout the initial screening and stabilizing treatment. This removes insurance status as an issue should the government later claim that the staff was motivated in some way or treated the patient disparately on the basis of financial class. It is easier to prove that actions were not predicated on the patient’s financial status when the actor lacks knowledge of that status than to prove that the actions were medically appropriate despite knowledge that the patient had no insurance.

After the MSE and initiation of stabilizing treatment, insurance status and ability to pay can be considered in determining the patient’s future care, such as hospital admission, transfer, or discharge and follow-up.

Documentation

EMTALA is a technical law, and compliance with the technicalities requires proper documentation. Furthermore, clinical outcomes are irrelevant under government enforcement, and compliance is not presumed; the hospitals must prove compliance through documentation.

Central Log

Hospitals must maintain a central log of all patients presenting to the ED requesting examination or treatment. The log must contain the name and disposition of the patient, including whether the patient refused treatment, whether the hospital refused to provide an MSE or treatment, and whether the patient was admitted, treated and stabilized, transferred, or discharged. The purpose of the log is to permit CMS and the state surveys to select and review individual records to investigate whether the hospital is in compliance with the law.

The log must include all persons presenting to the hospital's dedicated EDs, whether on or off campus. These areas include the typical ED, freestanding emergency centers, labor and delivery suites, ambulatory care or fast track areas contained in the ED, and psychiatric intake centers. The logs are not required to be collated into a single document but must be retrievable at CMS’s request.

Medical Record

All areas of the hospital used to conduct the MSE must create a medical record for the patient and keep a log of those presenting for examination and treatment. If members of the hospital medical staff see their patients in the ED, either on a scheduled or an unscheduled basis, the hospital must create a medical record and require the physician to document the care provided in that record. The physician’s private office records documenting care provided at the hospital are insufficient.

Most important, the emergency physician should document whether an EMC was determined to exist on every patient seen in the ED, even if the initial chief complaint is seemingly trivial. The legal purpose of the required MSE is to determine if an EMC is present. To facilitate documentation, ED charts should include two check boxes: one labeled “EMTALA EMC present” and the other “EMTALA EMC absent.” The person performing the MSE should check the appropriate box for each patient, and completion of this documentation should be a prime part of the ED’s quality improvement monitoring program.

Stabilization Requirements

Once the hospital determines that an individual has an EMC, EMTALA requires the hospital to either stabilize the EMC or, if it lacks the capability to stabilize the patient, to transfer the patient to another medical facility that can provide the necessary treatment. A sample form for use in documenting such transfers and patient consent to transfer is shown in Figure 202-1.)

When and if the patient is “stabilized” has significant ramifications for hospitals and physicians, because once patients are stabilized, EMTALA no longer applies. After stabilization, hospitals are free to refuse to provide further treatment or to transfer stabilized patients for purely financial reasons. On-call physicians can refuse to treat or admit stable patients or insist that stable patients be transferred owing to their lack of insurance. An MCO can refuse further payment to the hospital and request that the stabilized patient be transferred to one of its contracting facilities.

However, other federal, state, or local standards may govern further treatment or transfer of ED patients. For example, state laws often prohibit hospitals from transferring patients for any reason except that they are incapable of handling the patient’s medical problem.

Two elements must be present to trigger EMTALA's stabilization requirement: (1) the patient must have an EMC, as defined by law, and (2) the hospital must determine that an EMC exists. That an EMC exists is not sufficient to invoke the duty to stabilize; the hospital also must have actual knowledge that the EMC is present. Actual knowledge is a legal term that means the examining physician subjectively believed that an EMC existed. It is not the commonly understood objective standard used in malpractice cases, wherein liability is predicated on whether the physician knew or reasonably should have known the patient had an emergency condition. Whether the physician’s judgment was negligent, or even grossly negligent, is irrelevant under EMTALA. The subjective perception of the examining physician controls whether EMTALA’s stabilization requirement is triggered.

The appellate courts have uniformly held that if an EMC is not detected, the hospital has no stabilization duty and cannot be charged with failure to stabilize the patient’s condition. Furthermore, consideration or suspicion that an EMC may exist does not rise to the level of actual knowledge. If the hospital fails to detect an EMC through its standard screening procedures, the patient has only a state malpractice claim of “failure to diagnose” and not a federal cause of action for “failure to stabilize” the emergency condition. Once the physician or hospital does diagnose an EMC, however, the courts will allow a failure-to-stabilize claim to be brought in federal or state court under EMTALA.

This aspect of EMTALA is distinctly different from ordinary malpractice. Documentation in the medical record of “no EMC present” eliminates all further liability under EMTALA;
Emergency Medical Condition (EMC) Identified: (Mark appropriate box(es), then go to Section II) [Dr. Bitterman - 2008]

I. MEDICAL CONDITION: Diagnosis ______________________________________________________________________

☐ No Emergency Medical Condition Identified: This patient has been examined and an EMC has not been identified

☐ Patient Stable - The patient has been examined and any medical condition stabilized such that, within reasonable clinical confidence, no material deterioration of this patient's condition is likely to result from or occur during transfer.

☐ Patient Unstable - The patient has been examined, an EMC has been identified and patient is not stable, but the transfer is medically indicated and in the best interest of the patient.

I have examined this patient and based upon the reasonable risks and benefits described below and upon the information available to me, I certify that the medical benefits reasonably expected from the provision of appropriate medical treatment at another facility outweigh the increased risk to this patient's medical condition that may result from effecting this transfer.

II. REASON FOR TRANSFER: ☐ Medically Indicated ☐ Patient Requested ______________________________________________________________________

☐ On-call physician refused or failed to respond within a reasonable period of time.

Physician Name: _______________________________ Address: ______________________________________________

III. RISK AND BENEFIT FOR TRANSFER:

Figure 202-1. Emergency Medical Treatment and Active Labor Act (EMTALA) hospital transfer form.
EMTALA's requirement to provide on-call physicians no longer extends to inpatients diagnosed with an EMC. Other Medicare conditions of participation govern inpatient care, and hospitals certainly should implement policies and procedures for providing emergency specialty services to patients in whom an EMC develops after admission to the inpatient setting.

### Disposition Issues under EMTALA

#### Admission

Admitting the patient to the hospital ends the hospital’s duty under EMTALA, unless the admission is a ruse to avoid the hospital’s EMTALA responsibilities. As noted earlier, admission to “observation status” does not meet CMS’s regulatory definition of “admitted,” so EMTALA still applies to the care of observation patients in the inpatient setting, as well as those in an ED observation or chest pain unit.

Once the emergency physician determines that the patient needs to be hospitalized, the patient’s physician or the appropriate on-call physician should be contacted. If the admitting or on-call physician disagrees with the emergency physician’s judgment, it is incumbent on the admitting or on-call physician to come to the ED to personally examine the patient. This fact should be mutually understood by the entire medical staff and the hospital administration and should be written into hospital policy and procedure.

#### “Discharge” or Transfer to Home

Under EMTALA, any patient movement away from the hospital is legally defined as a “transfer.” Thus, from a legal perspective, all patients discharged from an ED are considered to have been transferred. Sending a patient home after treatment in the ED who is retrospectively determined to be unstable is considered to represent a transfer of an unstable patient and, as such, a violation of EMTALA. To avoid such retrospective analyses, emergency physicians should document that no EMC was found or that the patient was stable on discharge. If the patient leaves without permission, the hospital has not legally transferred the patient.

#### “Discharge” or Transfer from the Emergency Department to an On-Call Physician’s Office

Because all discharges from the ED are defined as transfers under EMTALA, so too are discharges from the ED sent directly to an on-call physician’s office for acute intervention. CMS looks askance at transferring patients away from the hospital to a physician’s office for acute procedures that could have been done in the ED or in the hospital. Ophthalmologist services may constitute an exception, because although the ED may have rudimentary eye tools, ophthalmologist typically have much better equipment in their offices for examining patients with eye complaints to determine whether an EMC is present or to treat emergency conditions. In essence, movement to the office in these cases becomes a medically indicated transfer to receive a higher level of services than the hospital can provide. CMS accepts such movement, so long as the ED arranges a formal transfer in compliance with EMTALA, as noted later on.

CMS’s view is extremely unsatisfactory, particularly to orthopedic surgeons. It is standard practice in most hospitals for the emergency physician to splint various displaced fractures and send the patient to the on-call orthopedic surgeon’s office for reduction of the fracture and further necessary treatment. CMS believes that the orthopedic surgeon should
perform the reduction and treatment at the hospital in each case, because the surgeon’s office has no resources that the hospital lacks.

However, EMTALA applies only if the EMC is unstable at the time of transfer. If the ED “stabilizes” the fracture, EMTALA’s obligations end. Thus, it is reasonable to send patients to the office for further treatment, so long as they meet the legal definition of “stable at the time of discharge” from the ED. The determination of whether the patient is stable for transfer to the orthopedist’s office rests solely on the judgment of the examining emergency physician. If the patient has accompanying injuries or is too uncomfortable to be moved, or if the emergency physician believes the injury is such that the patient should not travel, then the orthopedic surgeon should be asked to care for the patient in the ED. 9

Follow-up Care

Obtaining follow-up care for discharged ED patients, particularly indigent persons and Medicaid recipients, is a significant problem for nearly every hospital. However, EMTALA does not reach the on-call physician’s office in this scenario. If the patient does not have an EMC or is stable at the time of discharge, EMTALA does not apply from that point forward, and the on-call physician has no legal duty under EMTALA to see the patient in the office.

The real issue in ED follow-up is the level of commitment the hospital and medical staff are willing to make to the community. If the administration, the board, and the medical staff are comfortable with their decision, and if they have acted in the best interests of the patients they serve, they should have no trouble defending their actions to CMS or any other entity.

Whatever decision the hospital and physicians make regarding ED follow-up duties, they should explicitly define those responsibilities in the medical staff bylaws or hospital rules and regulations, so that all personnel understand, in advance, what it means to be “on call” for the ED at that hospital.

ED discharge instruction sheets also should include a fail-safe clause advising patients to return to the ED if their condition deteriorates before seeing the referral specialist or if the follow-up arrangements disintegrate for any reason. Such a statement could help the hospital avoid liability when the on-call specialist fails to implement the prescribed follow-up plan.32

Transfers to Other Acute Care Hospitals

Before transferring any patient out of the ED, the emergency physician must first determine whether the patient is stable, as defined by law. EMTALA regulates the transfer of unstable patients only; it does not apply to the transfer of stable patients. 2,9 If no EMC is found, the patient is considered stable. The determination of whether a patient is stable must be made at the time of transfer to be valid under the law.31 Unstable patients can be transferred for only one of two reasons: if the transfer is medically indicated, or if the patient requests the transfer. 9 There is no “managed care transfer of an unstable patient” or even of a stable patient.

Patients usually are transferred out of the ED because the transferring facility lacks the capability or the resources necessary to treat the identified EMC. Examples of patients best served by transfer are the head-injured patient in a hospital without a neurosurgeon on staff, the pregnant woman who needs the services of a high-risk obstetric center, and the multiple-trauma patient treated initially in a rural ED who requires treatment at a level 1 trauma center.

EMTALA defines such transfers as “medically indicated transfers,” because the purpose of each transfer is to obtain a higher level of medical care necessary to treat the patient's condition that is not available at the transferring facility. EMTALA governs almost every aspect of medically indicated transfers, including requiring hospitals to adopt and enforce policies to ensure compliance with federal transfer laws and mandating specific actions by the transferring and receiving hospitals (summarized in Boxes 202-1 to Box 202-3).1-3,53-55

---

**Box 202-1**

**Recommended Procedures for the Transferring Facility**

1. Stabilize the patient whenever possible.
2. Complete a physician certificate of transfer, including the risks and benefits of transfer.
3. Obtain the patient’s informed consent to the transfer.
4. Arrange for another hospital and physician to accept the patient in transfer.
5. Send appropriate data to the accepting facility (e.g., medical records, test results, transfer forms).
6. Arrange the transfer through qualified personnel, with use of appropriate transportation equipment.
7. Maintain records of all transfers for 5 years.

**Box 202-2**

**Invalid Reasons for Refusing an Appropriate Patient Transfer**

- Lack of insurance or out-of-network managed care plan
- Lack of citizenship
- Veteran status
- Patient’s physician not on staff
- Transferring hospital is out of network or outside hospital’s defined referral area
- “We are not an affiliated hospital”
- “We are not a specialty hospital”
- “We are a specialty hospital, but that’s not our specialty”
- “We are not the trauma center”
- Transfer originating out of county or out of state (including transfer of out-of-state Medicaid patients)
- EMS skipped over closer hospital
- Another hospital refused the transfer in violation of the law
- Another hospital’s on-call physician refused to respond to its ED in violation of the law

**Box 202-3**

**Recommendations for the Facility Asked to Accept the Patient in Transfer**

1. Accept all appropriate requests for transfer, regardless of whether the patient is an ED patient or an inpatient of the hospital.
2. Have a formal system for accepting or rejecting transfer requests, and document the reasons for any refusal to accept a patient in transfer.
3. Maintain records of all transfers for 5 years.
4. Report all EMTALA transfer violations to CMS.

ED, emergency department; EMS, emergency medical services.

---

CMS, Centers for Medicare and Medicaid Services; ED, emergency department; EMTALA, Emergency Medical Treatment and Active Labor Act.
Some states have enacted their own transfer laws. Most state laws parallel EMTALA, but some are even more restrictive, so physicians responsible for patient transfers should be aware of the controlling laws and regulations in their own state as well as federal law.

### Duty to Accept Appropriate Transfers from Other Hospitals

Medicare-participating hospitals that have specialized capabilities or facilities are required by EMTALA to accept appropriate transfers of patients who require such capabilities or facilities, if the hospital has the capacity to treat the patient. The duty to accept patients in transfer is a problematic issue for many larger, tertiary care, or academic hospitals as a result of the on-call specialty coverage crisis in the United States. Numerous hospitals have lost full or partial on-call coverage for specialties such as neurosurgery, orthopedic surgery, maxillofacial surgery, neurology, plastic surgery, and hand surgery. CMS’s softening of its EMTALA on-call regulations in late 2003 accelerated the trend of physicians’ simply taking fewer call nights at many smaller to medium-sized hospitals, forcing still more transfers to access emergency specialty care. (As confirmed in recent surveys, these changes have accelerated physician and hospital abandonment of on-call services, increased the risk of harm to patients needing specialty care, caused more delay in patient access to specialty care, and increased the number of patient transfers.) Specialty hospitals also enticed physicians away from acute care hospitals, in part because the physicians could decrease their on-call burden. However, CMS now requires specialty hospitals to accept appropriate transfers even if the specialty hospital lacks an ED.

### When Must a Receiving Hospital Accept a Patient in Transfer?

A Medicare-participating hospital must accept “medically indicated transfers” if it has “specialized capabilities or facilities” and the “capacity” to care for the patient. Medically indicated transfers (see definition in the previous section on stabilization) are ones for which a physician determines the patient has an EMC and needs to be transferred to obtain a higher level of medical care necessary to treat the patient’s condition that is not available at the transferring facility. Specialized capabilities or facilities are essentially any resources, other than a routine admission bed, or physician services available at an accepting hospital but not available at the transferring hospital. Capacity is rather generously defined by CMS to include whatever a hospital customarily does to accommodate patients in excess of its occupancy limits. For example, if a hospital customarily moves patients to other units or calls in additional staff, then it has in fact demonstrated the ability to provide services to patients in excess of its occupancy limits.

### Who Accepts Patients on Behalf of the Hospital?

The duty to accept appropriate transfers is a hospital duty, not a physician duty, and EMTALA does not require that a physician accept the patient. The hospital must create a formal system designating who is authorized to accept or reject patients on its behalf. It is strongly recommended that hospitals do not use the individual physician on call for each specialty alone to accept or reject patients in transfer. Hospitals should involve an administrative person or an emergency physician in addition to or instead of the on-call physician, to avoid inappropriate referrals. Because the duty to accept rests with the hospital, any inappropriate refusal by an uninform ed or rogue on-call physician subjects the hospital to termination from Medicare, civil monetary penalties, or civil liability if the patient is harmed because of the refusal to accept the patient in transfer.

The hospital should define the resources and capacity of the institution, and the times during which those resources are available. When necessary resources or capacity are not available, the hospital must in a timely manner inform the persons charged with accepting or rejecting transfers. The hospital should also educate appropriate personnel in its known referral facilities on the proper procedure to transfer patients into its system, including informing them of who is and who is not authorized to accept patients in transfer on behalf of the hospital. The hospital must educate its medical staff, particularly its on-call physicians and emergency physicians, regarding their responsibilities under EMTALA, including the responsibility to accept patients in transfer from other facilities on behalf of the hospital.

### Does a Hospital Have to Accept Transfers of Inpatients from Other Hospitals?

CMS says no. In late 2008, CMS issued regulations stating that no hospital has a legal duty under EMTALA to accept an inpatient in transfer from another hospital. Therefore, even if a requested hospital could treat an inpatient’s emergency condition that the transferring hospital is unable to treat, it may refuse the transfer for any reason and not be in violation of EMTALA.

However, the issue is certain to be litigated and decided by the courts. It is inevitable that an inpatient will develop an emergency medical condition and proceed to die or suffer severe damages because no other hospital would accept the patient in transfer due to lack of insurance. The patient or family will sue the hospital that refused to accept the patient in transfer, claiming that the hospital had a federal duty under EMTALA to accept appropriate transfers of patients with emergency conditions if the transferring hospital couldn’t treat the emergency. The transfer acceptance section of EMTALA was not part of the law when it was originally enacted. Congress later amended the law, calling it the “non-discrimination” section, because tertiary and academic referral hospitals were refusing to accept patients in transfer from other hospitals, leaving the patients to die in community EDs. It remains to be seen if the courts will ultimately interpret EMTALA contrary to Congress’s “non-discrimination” intent for patients with life-threatening emergencies.

### When Can a Hospital Refuse to Accept a Patient in Transfer?

There are only five reasons a hospital can refuse a request for transfer under EMTALA.

First, if the transfer is not a “medically indicated transfer,” a hospital can decline the transfer. Non-medically indicated transfers include patient-requested transfers and lateral transfers for any reason (lateral meaning that both hospitals have the same ability to handle the patient’s EMC), such as managed care transfers or family- or physician-requested transfers. Any time the sending facility can handle the patient’s EMC, a hospital requested to accept the patient in transfer can lawfully decline.

Second, if the hospital does not have the “capacity,” as defined by CMS, to accept the patient in transfer, it may and generally should refuse the transfer.
Third, if the transferring hospital is located outside the boundaries of the United States, the hospital has no legal obligation under EMTALA to accept the transfer. No other territorial limits are imposed on the duty to accept transfers; out of county, out of state, and out of the hospital’s designated referral area all are unacceptable reasons to refuse patients in transfer under EMTALA. Moreover, a hospital cannot refuse to accept a transfer just because the sending hospital is “skipping over” other hospitals to send the patient its way.

Fourth, if the transfer is not “appropriate,” the hospital may refuse to accept the patient in transfer at that time. This more vague reason takes into account the patient’s condition at the time of transfer and the time, distance, and “skipping over” other hospitals necessary to receive a hospital. For example, a trauma patient may need intubation and a chest tube inserted before the transfer is “appropriate,” or traveling 100 miles with hypotension from a ruptured abdominal aneu- rysm may be not be “appropriate” if closer hospitals are capable of repairing the aneurysm.

Fifth, the patient has been “admitted” to the hospital as defined by CMS.

There are no other reasons for which a hospital may refuse a request to accept a patient in transfer from another acute care hospital under EMTALA. Furthermore, no “contingencies” are allowed to be placed on the acceptance of a transfer. The receiving hospital may not condition acceptance of the patient on the transferring hospital’s agreeing to take the patient back once the emergency condition is resolved, may not require that the transferring hospital have additional consultations completed before the emergency physician transfers the patient, and may not require the transferring hospital to use the receiving hospital’s transport ambulance or helicopter service as a condition for accepting the patient.

Also, refusals of appropriate transfers on the basis of the patient’s insurance status or delaying appropriate transfers until the transferring hospital obtains authorization for payment from the patient’s managed care plan are definitely illegal under EMTALA.

### Duty to Report Transfer Violations

Any time a hospital has reason to believe it may have received a patient transferred in an unstable condition from another hospital, in violation of EMTALA, it must report the transferring hospital to CMS. The duty to report rests with the hospital, in violation of EMTALA, it must report the transferring hospital to CMS. The duty to report rests with the hospital, in violation of EMTALA, it must report the transferring hospital to CMS. Furthermore, no “contingencies” are allowed to be placed on the acceptance of a transfer. The receiving hospital may not condition acceptance of the patient on the transferring hospital’s agreeing to take the patient back once the emergency condition is resolved, may not require that the transferring hospital have additional consultations completed before the emergency physician transfers the patient, and may not require the transferring hospital to use the receiving hospital’s transport ambulance or helicopter service as a condition for accepting the patient.

Also, refusal of appropriate transfers on the basis of the patient’s insurance status or delaying appropriate transfers until the transferring hospital obtains authorization for payment from the patient’s managed care plan are definitely illegal under EMTALA.

### CONSENT FOR MEDICAL CARE

#### Informed Consent

The doctrine of informed consent is a fundamental principle of the American legal system: “Every human of adult years with a sound mind has a right to determine what should be done with his own body.” Physicians may not examine or treat any person without consent, and that consent must be informed. This means that the patient must be given all pertinent (“material”) information concerning the nature, risk, and alternatives of the treatment before that patient can be deemed to have effectively consented to the medical intervention.

Physicians should always endeavor to obtain informed consent yet remain cognizant of the significant limitations on and multiple exceptions to the doctrine, especially in the ED setting. Delaying treatment in an emergency to obtain informed consent is a much more serious and common medi-colegal problem than failure to obtain proper informed consent.

The law of informed consent contains a great deal of uncertainty, with many gray areas. Different states have different views, either in their statutory laws (legislation) or in their common law (judge-made law or precedent), on the meaning of “informed consent” in the care of the ED patient. Most cases are unique and depend on the specific circumstances.

Emergency physicians rarely have time to seek legal consultations, let alone wait for a court to render a decision concerning the legal nuances of consent issues. In these situations, it is helpful for emergency physicians to use a “when-in-doubt” rule to guide their immediate actions. This rule simply states that when emergency physicians are in doubt regarding the legality of a situation, “they should do what they believe to be in the patient’s best interest and worry about the legal consequences later.” Although emergency physicians risk criminal and civil charges of false imprisonment, battery, and even negligence suits for failure to obtain appropriate informed consent, the courts almost universally rule in favor of physicians who act in good faith on behalf of their patients in emergency situations. Successful civil litigation regarding an issue of consent theory against an emergency physician acting reasonably, and consistent with the appropriate standard of care, is extremely rare. An emergency physician is much more likely to be sued for failure to treat while waiting for consent than for providing reasonable treatment without consent.

#### Federal versus State Laws

Both federal laws (e.g., EMTALA) and state laws govern consent. EMTALA comes into play primarily in the evaluation of minors and with patient refusal of an examination, stabilizing treatment, or transfer. State consent laws vary widely and may be set by statutes or case law, or both. The concepts discussed next are generally applicable to emergency medical care, but all emergency physicians should learn the consent laws specific to their own state.

The law presumes that an adult is mentally competent to make medical decisions and that the competent adult is entitled to sufficient information to make an informed decision concerning the physician’s proposed course of examination and treatment. Under the doctrine of informed consent, physicians have the duty to disclose the following information to patients:

1. The patient’s condition and/or diagnosis
2. The nature and purpose of the proposed treatment, including the likelihood of success in the physician’s practice
3. Reasonable alternative measures related to the diagnosis and treatment, including the probable outcome of those alternatives
4. The particular known inherent risks that are material to make an informed decision about whether to accept or reject the proposed treatment, including the consequences of refusing that treatment

#### “Reasonable Person” versus “Professional Disclosure” Standard

The states are split on the standard used to determine what should be disclosed for patients to make informed decisions, but most require the “reasonable person standard” of disclosure. Under this standard, a physician must disclose all of the
Physician’s Role in the Consent Process

The physician who proposes to undertake the procedure must be the one to obtain the patient’s informed consent. The duty to obtain consent cannot be delegated, so physicians cannot ask nurses or other health care providers to obtain patients’ consent on their behalf. The physician who will care for the patient is best qualified to discuss the treatment and its risks and benefits with the patient. Nurses, as well as physicians not skilled in performing the procedure, cannot obtain valid informed consent.

The physician should write or dictate into the patient’s medical record a summary of the discussion held with the patient and family concerning the elements of informed consent. Particular attention should be made to documenting those material risks discussed with the patient before obtaining the patient’s consent.

Consent is a process, not a signature. A written, signed, separate consent form is not legally required under the doctrine of informed consent; however, hospitals may require emergency physicians to complete standardized consent forms and obtain the patient’s signature. The signed form is not a substitute for the consent process. It cannot replace the exchange of information that occurs between the physician and the patient and family, the answering of questions, and the ultimate agreement of the patient to undergo the medical or surgical intervention.

A signed, written consent form, however, does constitute some evidence of a valid consent. In some states, a signed consent form is presumed to represent valid consent unless that presumption is rebutted by proof that the consent was obtained by fraud, deceit, or misrepresentation of material fact.

Implied Consent in Emergency Situations

If an unconscious or incapacitated patient cannot express consent, the law will assume the patient consented to treatment for the emergency situation. Implied legal consent is premised on two principles: (1) duty to obtain informed consent is excused if death or irreparable harm may result if the physician delays providing treatment, and (2) the law presumes that a reasonable, competent, lucid adult would consent to lifesaving treatment.

The emergency treatment allowed is limited to the circumstances of the emergency, however, and only treatment required to resolve the emergency should be undertaken without consent. Similarly, the emergency condition must require immediate medical attention, with insufficient time to inform the patient or seek consent from another person.

Courts differ on the definition of a “true emergency,” and whether the emergency exception applies in a given case depends on the definition accepted by the court and the application of that definition to the particular set of facts. Fortunately, the courts generally will stretch the doctrine to protect physicians who act in good faith in caring for a patient with a perceived emergency condition. This is one situation in which use of the “when-in-doubt rule” and documentation of the physician’s concerns will weigh greatly in the court’s determination of whether the physician acted appropriately without obtaining informed consent. Physicians can further protect themselves by obtaining a second opinion that a true emergency exists.

Minors

Minors Accompanied by a Parent or Legal Guardian

Parents and legal guardians have the right to consent on behalf of their minor children. However, they must act reasonably and in the best interests of their children. If they do not, their right to consent can be abrogated by the state or the courts. Parents are not allowed to refuse treatment for a child with a life-threatening emergency condition. The management of children with emergency conditions whose parents refuse to give their consent to treatment is discussed later.

Either natural parent of the minor child may provide legally binding consent. If one parent agrees with a proposed treatment and the other does not, consent may be accepted from the agreeing parent. Even if separated or divorced, either parent may give consent unless one parent has been judicially granted sole legal custody of the child, in which case only the custodial parent may consent. The child’s biologic father, even if never married to the mother, also may consent for his child.

Unaccompanied Minors

EMTALA mandates that all persons presenting to an ED requesting care be examined to determine whether an emergency condition exists. Because EMTALA is federal law, it takes precedence over all state consent laws regarding the initial evaluation of a minor child. In essence, the child’s mere presence at an ED requesting examination or treatment constitutes legal consent to examine the child to determine whether an EMC is present. Furthermore, the hospital should never delay this initial screening evaluation in order to wait for consent from a parent or legal guardian (and nurse triage does not count as the required medical screening, no matter how nonurgent the child’s condition appears to the nurse).

If an EMC is discovered through the initial screening examination, the physician may treat the emergency under either state or federal legal theories. First, under state laws the standard emergency exception doctrine applies. State laws allow physicians to proceed with treatment whenever an emergency exists. Although no uniform legal definition of emergency exists among the states, state laws tend to define an emergency very liberally, such as “any threat to the minor’s life or health.” The courts almost always affirm a physician’s judgment regard-
ing an emergency condition and rarely question the treatment given to a minor without parental consent. Preserving life, preventing permanent disability, alleviating pain and suffering, and avoiding eventual harm have been used as guidelines for emergency treatment without consent. Any minor presenting to the ED should be triaged and provided with an MSE to determine whether an EMC exists.

Under EMTALA, if an EMC is present, the hospital and physicians must provide “stabilizing treatment.” Federal law also gives the physician broad discretion to decide what treatment should be performed and in what timeframe it should be accomplished. The stabilization requirement includes transfer as necessary to an institution capable of handling the minor’s emergency condition. Thus, under federal law, a minor could be examined, stabilized, or transferred to another institution without consent ever being obtained from the family; in this instance, the care would be not only in the patient’s best interest but also legally mandated.

Generally, if the MSE does not reveal an emergency condition, physicians need to obtain proper consent from the minor’s parents or legal guardian. However, state laws and the courts have applied a number of exceptions to allow minors to seek treatment on their own without parental consent. These exceptions vary widely from state to state, and most are applied through an analysis of facts and circumstances on a case-by-case basis by the courts. Under the minor exception, minors who possess an understanding and appreciation of the nature and consequences of the treatment and appear competent to make their own decisions are allowed to consent, despite not having reached the defined age for maturity (usually 18 years). A minor mature usually is 15 to 17 years old.

The emancipated minor provides another exception to the need for parental consent. If the minor is living independently, is self-supporting, or is in the U.S. Armed Forces, the courts may recognize the minor as emancipated and able to consent on his or her own behalf. Again, this is determined by the courts on a case-by-case basis. Additionally, most states have statutory reasons, such as sexually transmitted diseases, pregnancy, or domestic violence injuries, that allow minors to seek care without the consent of their parents.

**Incompetent or Incapacitated Adults**

If a person has been declared legally incapacitated by a court, consent must be obtained from the person’s court-appointed legal guardian. In addition, people may appoint legal surrogates to make legal decisions for them should they become incompetent. State-sanctioned living wills, advance directives, and durable medical power of attorney documents all transfer consent powers from a person who becomes incompetent to a legally appointed surrogate.

If an incompetent adult has neither a legal guardian nor an appointed surrogate, physicians typically look to the patient’s family for consent to treatment. However, consent to treatment by a family member, even the patient’s spouse, generally is not acceptable under American law unless the spouse or family member has been appointed legal guardian by a court of proper jurisdiction. Marriage does not confer one spouse the legal capacity to consent to medical treatment for the other spouse, even when the ill or injured spouse is incompetent.

Some states recognized this problem and enacted “family consent statutes,” which outline a hierarchy of family members who can legally provide consent when the family member becomes incapacitated. However, even when families have no legal standing to consent for the incompetent relative, it is always wise to involve family in the medical decision-making process. Communication and concern for the family will avoid misunderstandings, surprise, and anger, which are the primary sources of litigation. Fortunately, if an emergency exists, no authorization from family is necessary to provide such reasonable care as is necessary to correct the life-threatening situation. Once the emergency is resolved, consent should be obtained from someone authorized to act on behalf of the incompetent patient. If there is no appointed legal guardian or surrogate and no state statute on family consent, the physician will need to seek consent authorization from the courts. The courts may appoint a guardian at that time, generally a family member, or after judicial review of the issues, the court itself may grant consent on behalf of the incapacitated person.

**Other Special Patient Populations**

**Prisoners**

Competent prisoners generally do not surrender the right to consent by virtue of being incarcerated. However, a state or court may compel treatment based on interests perceived as paramount to the prisoner’s interests. The elements usually necessary to treat self-inflicted injuries over the objection of the competent prisoner include the following:

1. The injury to the prisoner was willful and intentionally self-inflicted.
2. The proposed treatment is necessary to preserve or restore the health of the prisoner.
3. The prisoner refuses to give consent.
4. The physician documents the medical indications for treatment in writing in the prisoner’s medical record.

**Alcohol-Intoxicated Patients**

Alcohol intoxication itself may not render a patient incompetent to give informed consent. The emergency physician must evaluate each situation individually to determine whether the patient is incapacitated by alcohol to the extent that he or she is no longer able to understand the proposed treatment, risks and benefits, and rational alternatives. In essence, the general rules for determining whether a patient is competent to make informed decisions cannot be disregarded just because the person is intoxicated with alcohol. However, the “when-in-doubt rule” is particularly applicable in these cases because alcohol intoxication often is associated with occult serious illness or injury.

Alcohol intoxication, particularly if documented by a measured blood alcohol concentration (BAC), is strongly suggestive to courts and juries of impaired mental status, even though health care workers recognize that many alcoholics are entirely rational and competent at fairly high BACs. Low BACs do not guarantee competence, because other processes (e.g., hypoglycemia, blood loss, impairment from other illicit substances) may cause the patient to be incompetent. Thus, the patient’s clinical capacity is more important than the specific level of alcohol in determining competence.

One advantage of obtaining a BAC is that some states allow blood samples drawn solely for medical purposes to be subpoenaed later by the prosecutor for use against the driver in a driving-while-intoxicated prosecution or other criminal charges.

It is important to recognize that the state “legal limit” of intoxication is not a measure of a patient’s competence. The legal level for driving has little, if anything, to do with the
capacity to make informed medical decisions. However, this distinction is sometimes difficult for judges and juries to understand, and the emergency physician can actually use the level to support a judgment that the patient was not competent to make informed decisions in a particular instance. At other times, it is better not to have a “number,” so that the only relevant criterion for determining the patient’s competence is the physician’s judgment.25

Patients Given Pain Medications

Obtaining informed consent from patients treated with pain medications before a procedure is a common issue. As with alcohol intoxication, the mere fact that a patient has been given narcotic analgesia does not render that patient incapable of consenting to surgical procedures. Plaintiff attorneys can always argue “the patient was too snowed with drugs to give consent”; on the other hand, they can equally argue that the patient was “in too much pain to consent and would have agreed to anything to stop the pain.” Accordingly, when consent is sought from a patient who has received pain medication, the patient’s ability to understand the ramifications pertaining to the procedure should be assessed and taken into consideration, involving the family in the process if possible. The physician should document that the patient’s premedicated state was considered when judging the patient’s competence to make an informed decision.

■ REFUSAL OF MEDICAL CARE

Informed Refusal

The corollary to a patient’s right to give informed consent is the patient’s right to refuse medical care, even if such refusal results in death. In Cruzan v. Director, Missouri Department of Health, the U.S. Supreme Court determined that a competent adult has a constitutionally protected right to refuse medical care.96 However, that right is not absolute. Under particular circumstances, courts will consider countervailing compelling state interests, such as preventing suicide, preserving life, and protecting innocent third parties.

Physicians who honor a competent patient’s decision to refuse treatment are not liable for any resulting bad outcome.79 In fact, physicians are more likely to be successfully sued for treating patients over their objections or without their consent, even when the treatment is lifesaving. When a competent adult refuses indicated medical intervention, it often is because of fear, anger, misunderstanding, or some other failure in communication in the physician-patient relationship. Before allowing a patient to refuse care, the physician should try to determine and resolve the underlying reasons behind the patient’s refusal.

The attending physician must always be involved when a patient refuses medical care or expresses the intent to leave against medical advice.100,101

As with consent, refusal of medical care is a process, not a signature. It must be an informed refusal; merely having the patient sign an “informed consent to refuse examination, treatment, or transfer” form or an “against medical advice” form is not sufficient. The four essential components of the process are discussed next.

Determining Competence

The physician must determine that the patient is competent to make decisions. Normal findings on the mental status examination without evidence of diminished mental capacity from closed head injury, severe pain, hypoxia, hypotension, alcohol intoxication, mental retardation, or mind-altering substances constitute good evidence of competency. Noting the patient’s rationale for refusing care, even if it is not reasonable, provides additional evidence of competency.102

Ensuring an Informed Decision

To be legally binding, a decision to refuse a test or treatment or to sign out against medical advice must be an informed decision. The physician must explain the severity of the patient’s condition, the potential complications, and the alternative treatments available. The physician should use terms that the patient can understand and provide the patient an opportunity to ask questions. The patient must understand that the risks of refusing care include the possibility of permanent disability and death. Ideally, a witness should be present when the physician informs the patient and any family members.105

Involving Others

The patient’s family, friends, and personal physician should be involved whenever possible. These persons should hear the same message as that conveyed to the patient, because they may be able to persuade the patient to accept the recommended therapy. If the patient expressly forbids the emergency physician to speak with others, as is the patient’s legal right, this should be explained to them and documented in the medical record.

Documenting Appropriately

Appropriate documentation of the refusal process is necessary to protect the physician and hospital from inappropriate litigation. The patient should be asked to sign the refusal form.2,9,104 (Fig. 202-2 shows a sample AMA form.)

If the patient refuses to sign the form, that fact should be documented, and the form signed by a hospital representative who witnessed the patient’s refusal. The medical record should reflect the patient’s mental status examination findings and competency to make informed decisions, the risks and benefits of recommended treatments, the available alternatives, and the participating family or friends. Documenting the patient’s rationale for refusing treatment, that the patient was treated to the extent allowed by the patient, and that the patient was invited to return for care at any time offers added protection.104

Federal Rules

EMTALA requires hospitals to take and document specific actions when patients refuse medical screening, treatment and stabilization, or transfer. The government and the federal courts presume that the patient requested emergency care and place the burden of proof on the hospital to demonstrate that the patient voluntarily refused care.2,9,105

There are essentially two scenarios in which patients leave the ED after refusing examination or treatment. First, some patients simply pick up and leave, without the knowledge of anyone affiliated with the hospital. If the patient’s departure is witnessed, the patient does not respond to requests to return for the examination or to discuss the issues with the hospital staff. Hospitals generally refer to these patients as those who “leave without being seen” (LWBS) or “leave before examination.” In the second scenario, the hospital personnel are aware that the patient is about to leave and have an opportunity to
INFORMED CONSENT TO REFUSE EXAMINATION, TREATMENT, OR TRANSFER

I understand that the hospital has offered: (Check all that apply).

A. ☐ To examine me (the patient) to determine whether I have an emergency medical condition, or
B. ☐ To provide medical treatment or to provide stabilizing treatment for my emergency condition, or
C. ☐ To provide a medically appropriate transfer to another medical facility.

The hospital and physician have informed me that the benefits that might reasonably be expected from the offered services are:

________________________________________________________________________________________________________

________________________________________________________________________________________________________

and the risks of the offered services are:

________________________________________________________________________________________________________

________________________________________________________________________________________________________

Physician Documentation

☐ The patient appears competent and capable of understanding risks and benefits.

☐ Alternative treatments discussed with the patient.

☐ Patient’s family involved. ☐ Family not available. ☐ Patient does not want family involved.

Signature of Physician ________________________________

Patient or Legally Responsible Person Documentation.

☐ I have declined to have the physician fully explain to me the risks, benefits, and alternatives to leaving the hospital against medical advice. I knowingly and willingly take and assume the responsibility for all risks incurred.

or

☐ The physician has fully explained to me the risks and benefits but I choose to refuse the offered services. I understand that my refusal is against medical advice, and that my refusal may result in a worsening of my condition and could pose a threat to my life, health, and medical safety. I understand that I am welcome to return at any time.

[Hospital Addressograph or Sticker Goes Here] [Robert A. Bitterman, MD JD - 2008]

Figure 202-2. Leaving against medical advice (AMA) form: Informed consent to refuse examination, treatment, or transfer.
interact before the patient leaves. Hospitals generally refer to this as “leaving against medical advice.” The Office of the Inspector General (OIG) and CMS refer to both of these scenarios as “voluntary withdrawal” of the patient’s request for evaluation or treatment.2,9,106

**Leaving without Being Seen**

If a patient walks out before the MSE and later has an adverse medical result, the burden will be on the hospital to prove that the person left voluntarily and was not denied examination or treatment by the hospital. The OIG and CMS admonish hospitals regarding LWBS patients, stating that “hospitals should be very concerned about patients leaving without being screened. Since every patient that presents seeking emergency services is entitled to a screening examination, a hospital could violate the patient antidumping statute if it routinely keeps patients waiting so long that they leave without being seen, particularly if the hospital does not attempt to determine and document why individual patients are leaving, and reiterate to them that the hospital is prepared to provide a medical screening if they stay.”2,9

Hospitals need to have a policy and practice for LWBS patients that adequately document pertinent findings and protect the hospital from liability. In most hospitals, the staff calls the patient and checks the waiting area at least three times before declaring that the patient has left the department. These serial checks, with time of day performed, should be documented on the patient’s record, and once it is evident that the patient is no longer present, the record should be reviewed on a timely basis by the physician on duty. If the reviewing physician discovers something of concern regarding the patient’s chief complaint or triage data, the person can be contacted and encouraged to return to the ED. The registration papers, triage records, nursing documentation at triage, and the physician’s review and documentation of that review all should be kept in the patient’s permanent record. These records should be retained for a minimum of 5 years to protect the institution should the interaction ever be the subject of a retrospective EMTALA investigation or litigation on behalf of the LWBS patient.2,9

**Leaving against Medical Advice**

If hospital personnel are aware that a patient intends to leave before completion of the MSE or stabilizing treatment for whatever reason (e.g., tired of waiting, changes mind, concerned over cost of care), the hospital must contact and document the interaction carefully to avoid EMTALA or medicolegal liability.2,9,107-109 (Box 202-4) In each case, the following steps should be taken:

1. **Inform the patient of the hospital’s obligation under the law.** The ED staff should inform patients of their rights under the EMTALA to receive medical screening and any necessary stabilizing treatment from the hospital, regardless of their ability to pay for that service.
2. **Determine the patient’s competence.** Only legally competent persons can refuse necessary medical care. For example, an alcohol-intoxicated woman who presents to the hospital with a medical complaint cannot be allowed to leave the hospital without examination and treatment until it is determined that she is legally competent to make such a decision.
3. **Explain the risks and the benefits to the patient.** For patients to make an informed consent to voluntarily withdraw their request for services, they must understand the benefits and the risks of withdrawal before refusing examination and treatment. These risks and benefits should be specific to the patient’s chief complaint.
4. **Secure the patient’s written informed consent to refuse care.** The hospital should take all reasonable steps to secure the patient’s written and informed consent (i.e., obtain a signature) to refuse medical care. A standard form should be used that contains space for documenting the patient’s competence, the risks and benefits discussed, and whether the patient’s family was available to be involved in the discussions. If the patient refuses to sign the form and simply walks out after the interaction with the hospital, the person who discussed the issues with the patient and witnessed the patient’s refusal should sign the form and document the interaction.
5. **Offer alternative care within the scope allowed by the patient.** It is outside professional practice standards to respond angrily, act vindictively, or punish patients when they decide to leave against advice by refusing to provide alternative treatments, medications, analgesics, or discharge instructions. Patients always get to define the scope of medical services they are willing to accept. Accordingly, an appropriate strategy is to negotiate and cajole them into allowing the best possible care under the circumstances that they define. For example, if a patient with “fight bite” tenosynovitis refuses hospital admission, operative intervention, and intravenous antibiotics and analgesia, then the next best option can be offered, such as thorough cleansing in the ED, intramuscular antibiotics, and oral narcotics, with recheck in 24 hours. Failing that, cleaning in the home sink, oral antibiotics, acetaminophen, and follow-up with the patient’s primary care physician can be recommended.

Negotiation aims for the best alternative that the patient is willing to accept, even if that means providing
less than optimal treatment. Also, pain medications should never be withheld because the patient will not accept the recommended treatment plan. This “strategy” is cruel, further alienates the patient, and serves no useful purpose.

Moreover, patients should always be invited to return to the ED (or encouraged to see their private physician) if they change their mind and become willing to accept the recommended treatment. A patient’s refusal of the more appropriate treatments, as well as communication of offers to provide treatment within the circumstances prescribed by the patient, should be delineated.

6. Document the interaction in the patient’s hospital record. The medical record, preferably a dictated and transcribed medical record, should accurately relate the interaction between the hospital and the individual refusing the MSE. The record reflects the hospital’s conformity to the law and the patient’s leaving of his or her own accord—specifically, the risks of refusing the examination and the reasons for the patient’s refusal. Documenting the reasons for refusal provides evidence that the hospital did not economically coerce or in any way financially deter the patient from remaining for the MSE. The chart must clearly indicate that the patient did not leave the department based on a “suggestion” by the hospital concerning any financial issues.

Parent or Guardian Who Refuses Care or Blood Transfusions for a Minor

Generally, state laws support parental control of health issues affecting their children. However, the state will not allow parents to deny children needed emergency medical care under the doctrine of parens patriae, the state’s paternalistic interest in children. All states empower emergency physicians to intercede under their child abuse and child neglect laws. When a child’s injuries are potentially life-threatening, the emergency physician can take custody of the child under the child abuse laws and provide indicated treatment, including blood transfusions. In deciding whether to act, the “when-in-doubt rule” definitely applies, and all jurisdictions statutorily protect physicians from criminal and civil liability for acting in good faith to protect children.

The courts have specifically addressed the issue of Jehovah’s Witness parents attempting to refuse emergency blood transfusions for their minor children. All jurisdictions hold that a parent’s right to freedom of religion does not include the right to deny life-sustaining medical intervention for that person’s children. One judge best summarized the feelings of the courts: “Not even a parent has unbridled discretion to exercise his or her religious beliefs when the state’s interest in preserving the health of the children within its borders weighs in the balance.”

Some states specifically address the issue of overriding parental refusal of indicated medical intervention by statute. In North Carolina, for example, if the parents refuse to consent to treatment, and the delay to obtain a court order would seriously worsen the child’s physical condition or endanger the child’s life, and if a second physician agrees that the procedure is necessary to prevent immediate harm, a physician can render treatment without parental consent. If a second physician cannot be contacted before initiating treatment, the physician may still perform the indicated therapeutic intervention without parental consent.

Conversely, courts refuse to rule against the parents’ wishes when the child’s medical condition is not serious or life-threatening. If there is no life threat or potential for serious impairment, the parents’ refusal should be respected. Parental refusal of indicated nonemergency medical treatment is usually statutorily defined as “child neglect,” which is not legally sufficient to take custody of the child. Child neglect should still be reported to the appropriate authorities; treatment for the child can then be obtained under a court order.

Jehovah’s Witnesses

Adult Blood Transfusions

The approximately 1 million Jehovah’s Witnesses in the United States believe that blood transfusion destroys their relationship with God and forfeits their chance for eternal life; accepting transfusion is not a minor infracktion of their faith. They do not accept whole blood, packed cells, platelets, white cells, or plasma or autotransfusion of stored blood. Most will allow the use of crystalloids, albumin, hemophiliac preparations, immunoglobulins, dialysis, and heart-lung machines.

Jehovah’s Witnesses and the issue of blood transfusion present difficult medicolegal issues in the ED. State courts may have widely divergent views on the issue, and no clear-cut answers exist. However, the current trend is granting patients greater autonomy to refuse blood, even when the state asserts compelling interests to override a person’s refusal.

General principles of consent and the “when-in-doubt rule” apply, but hospitals and medical staff also should (1) develop policies and procedures in advance to resolve potential conflicts with the Jehovah’s Witness patients in the community; (2) coordinate the management of each case with hospital legal counsel, in contact with a judge who can issue court orders when appropriate, if time allows; (3) have other physician consultants write notes of agreement regarding the need to give blood; and (4) communicate effectively with patients and family, in advance when possible.

Competent Adult

The courts have found that “the competent adult has the right to refuse a transfusion regardless of whether his refusal to do so arises from fear of adverse reaction, religious belief, recalcitrance, or cost.” This applies “even though we may consider a patient’s beliefs unwise, foolish, or ridiculous.” However, even this right is not absolute. If the patient’s refusal conflicts with compelling state interests such as the preservation of life, the prevention of suicide, or the protection of innocent third parties, the courts may order transfusions despite the person’s objections. Interestingly, typical scenarios in which the courts overrode a competent person’s refusal included cases involving pregnant women, to protect the life of the fetus; mothers of young children, to promote the general welfare of the children; and a sole supporting father or mother, to prevent offspring from becoming wards of the state. Some courts, however, have significantly restricted the hospital’s or state’s ability to assert compelling interests challenging a competent person’s right of self-determination.

Unconscious or Medically Incompetent Adult

In an emergency, if the Jehovah’s Witness’s beliefs are unknown, physicians may transfuse the patient because consent will be implied under the emergency doctrine. It is irrelevant if the spouse, mother, or other family members adamantly refuse to allow the transfusion for religious reasons. The state’s compelling interest in preserving life outweighs the family’s expression of the patient’s religious preferences.

In the past, when a Jehovah’s Witness’s beliefs and transfusion preferences were known in advance, but the patient was
incompetent at the time of the emergency, the courts tended to support transfusion until the patient became competent and could refuse transfusion “contemporaneously.”112,124 The modern trend is to accept objective evidence of the patient’s wishes—for example, a signed card carried by the patient that identifies him as a member of the Jehovah’s Witnesses and sets out his religious objection to blood transfusion. The card may be accepted as adequate evidence of the patient’s intent, like a form of advanced directive, which is binding on hospitals and physicians. In at least six states, if the card is dated and signed before two witnesses, it is statutorily valid.125 Even if the blood refusal card does not conform to a state’s advance directive statute, it should be considered strong evidence, but not necessarily determinative, of the Jehovah’s Witness’s wishes. Advance directives are merely a means to express an individual’s rights and are not the exclusive means to express those rights legally.118,119 Jehovah’s Witnesses increasingly use state statutorily defined advanced directive methods to legally express their intentions.126 Emergency physicians should, however, be certain the card or advance directive actually belongs to the patient.

Of interest, no Jehovah’s Witness has successfully sued a health care provider to recover damages in cases in which blood was withheld on the basis of an apparently valid blood refusal card. Also, “criminal, civil, or professional misconduct liability has never been imposed on health care providers for forgoing treatment the patient did not want.”127

**REPORTING REQUIREMENTS**

All states require hospital EDs to report certain events or illnesses to local public health authorities.128 The state’s primary intent is to prevent the spread of communicable diseases, protect its citizens from disease and violence, and prosecute criminal acts. In each instance, the state statute overrides patients’ rights of confidentiality. The statutes typically also provide physicians with immunity from civil liability or criminal prosecution if the reporting is done in good faith.129

All EDs should maintain up-to-date lists of diseases and incidents that must be reported to the state. The process and responsibility for appropriate reporting should be clearly articulated in departmental policy.

**Communicable Diseases**

Typical communicable diseases that must be reported include those of epidemiologic concern, such as sexually transmitted diseases (including gonorrhea, syphilis, chlamydial infection, nongonococcal urethritis, and human immunodeficiency virus infection) and highly communicable illnesses (such as tuberculosis, hepatitis, pertussis, and recently methicillin-resistant *Staphylococcus aureus* [MRSA] infection). Emergency physicians also have a duty to warn patients with communicable diseases against activities that may spread the disease and should instruct them to inform contacts to seek evaluation and treatment. Physicians should adequately document such instructions in the medical record to prevent liability to third parties for failure to warn appropriately.

**Violent Acts**

Wounds, injuries, and illness resulting from criminal acts of violence must be reported to state agencies.130 Bullet wounds, powder burns, stab wounds, intentional poisonings, child abuse or neglect, sexual assaults, spousal abuse, domestic violence, and any suspicious injuries generally must be reported.

**Deaths**

All deaths must be reported to state or local authorities. Death under certain circumstances also must be reported to the county medical examiner. Typically these include (1) deaths from violence, poisoning, accident, suicide, or homicide; (2) any sudden death in someone in apparently good health or when unattended by a physician; (3) any death occurring in a jail, prison, or correctional institution or in police custody; and (4) any death occurring under suspicious, unusual, or unnatural circumstances.131 Fetal deaths also may have to be reported, usually if over 20 weeks’ gestation or the typical gestational period of possible viability.132

When a death requires a report to the medical examiner, the integrity of the scene and the body should be preserved. ED staff should disturb the body as little as possible, secure the patient’s belongings and any potential evidentiary materials, and leave in place medical interventions such as endotracheal tubes, nasogastric tubes, and central or peripheral intravenous lines. The medical examiner will determine whether the state will assert authority over the body, order an autopsy, or release the body to the family.133

Additionally, any death that occurs while the patient is “restrained or in seclusion for behavior management,” when it is reasonable to assume that the death is the result of the restraint or seclusion, must be reported to CMS.133,134 In the ED setting, this typically would involve use of restraint or seclusion as a last resort to address violent behavior presenting a risk to the patient, hospital staff, or others.

**Alcohol-Related Motor Vehicle Crashes**

At least six states (Hawaii, Indiana, Illinois, Pennsylvania, Rhode Island, and Utah) have mandatory reporting laws governing alcohol-related motor vehicle crashes.135 Many other states have laws permitting, but not requiring, EDs to report intoxicated drivers to authorities on the basis of a known BAC.135,136

**Animal Bites**

Most states require the reporting of animal bites, particularly dog and cat bites, to the local public health department. The states also generally require the reporting of bites by any animals known to be potential carriers of rabies, such as bats, raccoons, skunks, foxes, and cattle, to prevent cases of human rabies and control the spread of rabies within the animal community.137

**Substance Abuse**

A few states require reporting of substance abuse to local authorities.138

PERSPECTIVE

The maintenance of wellness is critical in achieving a satisfying and productive career as a competent emergency physician. Wellness can be defined as the optimal state of health and well-being achieved through the active prevention of illness. Emergency medicine as a specialty was still in its formative years when concerns first surfaced regarding the stressful and potentially unhealthful aspects of practice in this specialty and the impact such stressors could have on wellness and career longevity. Although experience has shown that large numbers of emergency physicians enjoy long and fulfilling careers, questions remain about how best to cope with the demands and stresses associated with the practice of emergency medicine.

This chapter presents an overview of wellness issues facing the emergency physician, divided into three main sections: major stressors, physician burnout and impairment, and strategies for promoting wellness in emergency practice.

CAUSATIVE FACTORS: MAJOR STRESSORS IN EMERGENCY MEDICINE

A variety of stressors contribute to the potentially unhealthful aspects of emergency medicine practice, both in practicing physicians and in physicians in training. These stressors generally relate to four aspects of emergency practice: (1) difficult patient and professional relationships, (2) diversity of practice elements, (3) diminished resources, and (4) difficult decisions.

Difficult Patient and Professional Relationships

Although the ability to provide care for a variety of acute and complicated patients under significant time constraints is a significant source of gratification for practicing emergency physicians, the challenges imposed on the doctor-patient relationship are unlike those in other specialties in medicine. In clinical practice, most physicians have the opportunity of establishing a sound relationship with their patients over a period of time; in the emergency department (ED), however, patient and physician are thrust together in a relationship that typically is of high intensity, short duration, and based on the circumstances of need. Many patients presenting to the ED often are under high levels of emotional stress, in pain, and suffering from anxiety and apprehension. They may have language barriers, organic brain syndromes, psychiatric illness, personality disorders, or altered behavioral states that make them more difficult to evaluate. They may be frequent users of the ED services well known to the staff, presenting with conditions such as hypochondriasis requiring an inordinate amount of time and resources. Communication and conflict resolution challenges between physician and patient may be considerable. Patients also may present a danger to the physician, manifesting any of a variety of emotional and psychiatric disorders, including chemical dependency disorders, sociopathic behaviors, personality disorders, and psychosis.

Issues of personal safety remain a major concern among ED personnel because practice in this setting is more likely to be associated with exposure to acts of violence, verbal or physical threats, a variety of potentially life-threatening infectious diseases, and acts of bioterrorism. Dealing with “difficult patients” can arouse in the emergency physician a variety of emotions that have a negative impact on the doctor-patient relationship, including fear, anger, helplessness, inadequacy, intimidation, vindictiveness, and even hatred. Although such feelings are understandable, they may become a considerable source of stress.

Professional relationships may likewise be stressful. Emergency physicians practice “fishbowl medicine,” allowing the entire range of their practice habits and decision-making to be in the full view of all members of the medical staff. Disputes can arise regarding patient management and disposition decisions, spheres of practice, referral practices, specialist on-call responsiveness, and care of the uninsured. Moreover, although a less prevalent attitude now than in the early days of the specialty, in some professional circles emergency physicians are not accorded peer respect among colleagues in other specialty areas. Professional status is occasionally an issue in dealings between emergency physicians and hospital administrators, in which the ED may be viewed as a less desirable location for resource allocation compared with other clinical services.

Relationships with other members of the ED staff also may be subject to strain. Because emergency medicine practice often is contractually based for physicians, the physician group often does not have the same degree of workplace “ownership” and supervisory authority as that enjoyed by physicians in a private practice. Nurses and ancillary personnel generally are not hired by the emergency physician group, and disputes may arise over issues of responsibility and control.
Diversity of Practice Elements

The “24/7” nature of emergency practice, coupled with the responsibility to treat all persons at all times, fosters a tremendously diverse practice environment. Work schedules typically include a broad mixture of irregularly assigned days, nights, weekends, and holidays. The practice environment often is chaotic. ED patient visits continue to climb in the United States, amidst a diminishing number of hospitals. ED overcrowding and diminished availability of inpatient beds can result in ED holding of admitted patients and long waits for new patients to be assessed and treated. ED overcrowding and capacity issues have worsened to the point of crisis in some communities. ED staff are subjected to a barrage of intrusive noises, including alarms, monitors, pagers, and telephones, as patients of all ages, presentations, and acuity arrive for evaluations at unpredictable intervals. This diversity often is cited by medical students and residents embarking on a career in emergency medicine as a challenging, attractive, and often beguiling feature of the specialty. The older practitioner, after years of struggling to maintain some degree of order within the department, amidst a pattern in recent years of increasing volumes and acuity of patients, may tend to view diversity as a major stressor.

Diminished Resources

In an attempt to maintain financial viability amidst an ever-changing environment driven by diminished reimbursement, managed care, uninsured patients, and increasing costs, most hospitals have had to implement cost-cutting measures. These measures have resulted in a number of important resource limitations with which the ED must contend. These include (1) diminished staffing of nurses, ancillary personnel, and social services; (2) burdensome cost containment policies and documentation requirements regarding access to diagnostic and treatment modalities and outpatient referrals, specialty consultations, and hospital admissions; (3) inadequate policies providing for the care and disposition of medically indigent patients; and (4) diminished reimbursement for services rendered. Nursing shortages have reduced the ability of some EDs to recruit, retain, and build a solid team of seasoned nursing professionals experienced in emergency medicine.

Difficult Decisions

Emergency physicians often need to make difficult decisions based on ambiguous or incomplete information. Difficulties in the decision-making process, appropriate concerns regarding patient safety, an intense desire to maximize medical outcomes, anxiety over the potential for medical mistakes, the pressure of decisions made under time constraints, and fear of litigation are additional stressors of major importance.

CONSEQUENCES: THE BURNED-OUT OR IMPAIRED PHYSICIAN

Burnout

The term burnout was introduced by Freudenberger in 1975 to refer to feelings of job dissatisfaction caused by work-related stress. It includes long-term physical and emotional exhaustion, resulting in diminished interest in the major activities of the job. Burnout is of special relevance to physicians because it undermines the integrity of the physician-patient relationship, which is the foundation of medical practice and essential to effective service. People in advanced phases of burnout are likely to experience decreased productivity, less satisfaction with work, higher job turnover, lower self-esteem, more physical symptoms, more troubled family relationships, and a variety of affective changes, such as hostility, anxiety, depersonalization, cynicism, and depression. Symptoms of burnout are thought to be potential precursors of more severe manifestations of impairment, including alcoholism, drug abuse, and suicide.

Several studies have documented moderate to high levels of burnout among certain populations of emergency physicians, and few emergency physicians would dispute the particular significance of burnout as an occupational hazard. Of note, however, burnout is not an inevitable consequence for all practicing emergency physicians, and effective strategies are available to avoid it. A randomized survey of 958 physicians conducted by the American Board of Emergency Medicine in 1999 found that most respondents were middle-aged emergency physicians, and most were quite satisfied with their careers; work stressors were graded as only moderate in intensity.

Additional information regarding the burnout process in emergency medicine is available either by accessing the website of the American College of Emergency Physicians (ACEP) (www.acep.org) or by directly contacting the ACEP Practice Management Department (800-798-1822).

Physician Impairment

Physician impairment exists when a physician’s professional performance is adversely affected because of mental or physical illness, aging, alcoholism, or chemical dependence. The Federation of State Medical Boards defines an impaired physician as one who is unable to practice medicine with reasonable skill and safety because of a mental illness; a physical illness or condition that adversely affects cognitive, motor, or perceptive skills; or substance abuse. It is estimated that 17,000 practicing physicians are afflicted with substance abuse problems in the United States and that 100 deaths annually among physicians are directly attributable to chemical dependency. Several studies suggest that alcohol and substance abuse may be more prevalent among emergency medicine residents and practicing emergency physicians than among other practitioners or specialties.

Impairment in a physician colleague often is difficult to detect. The recognition of a pattern of events, rather than a single precipitating incident, may be key to making the diagnosis. Difficulties that arise in the workplace often are preceded by a history of family difficulties, including frequent arguments, periods of separation, extramarital affairs, and divorce. Frequent job changes (“geographic cure”) and unexplained time intervals between periods of professional employment also may be signs of impairment. A high value usually is placed on maintaining the source of income, and erosion of hospital duties is one of the last things that may be affected. Patient care responsibilities become neglected, and the impaired physician may exhibit poor medical judgment. The problem may develop over a long period because strong elements of denial are usual among family members and associates, as well as in the impaired physician.

Following the ethical principles of beneficence and nonmaleficence, it is important to deal fairly and honestly with colleagues yet take appropriate actions to protect patients from health care providers who are impaired or incompetent or who engage in fraud or deception. The primacy of patient welfare and the role of the physician as patient advocate are critical here. Programs to detect and treat physician impairment have now been established in every state. A few states
LIFESTYLE BALANCE: WELLNESS STRATEGIES FOR THE EMERGENCY PHYSICIAN

The very qualities that characterize medically successful physicians—perfectionism, the drive to succeed, willingness to work long and irregular hours, and ideals of individual service and sacrifice—also may dispose them to neglect their own physical and emotional needs. The formulation of any comprehensive wellness strategy is based on the concept of lifestyle balance and involves the integration of professional goals and responsibilities with needs for self-care and development.33-35 Cultivation of lifestyle balance involves four basic elements, summarized in Box 203-1 and discussed next in some detail.

Promoting Wellness in the Workplace

A strong predictor of job satisfaction among professionals with demanding and stressful jobs is the degree to which they have control over the work flow and job responsibilities in their workplace. Emergency physicians can introduce more control over elements of their practice by (1) ensuring adequate physician and support staffing to accommodate patient load, (2) ensuring adequate input in the development of departmental policies and procedures, (3) cultivating relationships among physicians and staff, and (4) mitigating noise, light, space, crowding, wait times, and structural discomforts.36-37

The irregularity of scheduled hours is a major workplace issue for emergency physicians. Shift changes often are cited as a major cause of dissatisfaction within the specialty.12,36 Shift work is associated with a variety of adverse effects on physical and emotional health.38-40 These include an increased incidence of ulcer disease, depression, mood swings, drug and alcohol abuse, altered immune response, chronic hypertension, cardiovascular mortality, infertility in women, divorce, and work-related accidents and errors.41 Approximately 25% of persons in the North American population are shift workers, and research has shown that an estimated 20% of people cannot tolerate shift work.31-32 A variety of shift work strategies have been proposed as a means of mitigating these effects; these are summarized in Box 203-2.44

Professional support groups also can help emergency physicians with issues of coping and control over the stressful aspects of their practice. In the process of sharing relevant information, relating personal experiences, listening to others’ experiences, and providing sympathetic understanding, members of support groups can cope in a more effective manner. The ACEP has a Wellness Section devoted to consideration of such issues and has sponsored policies and programs to address them. The ACEP also has a speaker’s bureau consisting of members who are available to address a variety of wellness-related issues.

A particularly important form of support group relates to critical incident stress debriefing. Critical incidents are witnessed traumatic events that have sufficient emotional power to overcome the usual coping abilities of people exposed to them. Emergency medicine is a field in which situations occur that may cause physicians and other ED personnel, regardless of rank, years of service, or gender, to experience unusually strong emotional reactions that have the potential to interfere with their ability to function. These situations are referred to as critical incidents. Emergency physicians are continually being exposed to critical incidents, including serious multiple-casualty incidents, pediatric injuries or deaths, line-of-duty deaths, injuries to ED personnel, events of excessive media interest, and events involving victims known to ED personnel. The impact of a critical incident often goes unrecognized even after common stress reactions appear. Although physical and emotional stress reactions are often considered normal and usually will diminish in time, very intense or prolonged reactions may have adverse effects on physician and staff well-being.

Rescue personnel exposed to such critical incidents can be subject to the cognitive, emotional, and physical sequelae comprising the post-traumatic stress syndrome. Components of this syndrome include a continual reexperiencing of the

BOX 203-2

SHIFT WORK STRATEGIES

1. Work the same shifts as much as possible and keep the same sleep patterns. Compensation should be increased for those willing to work night shifts for extended periods.
2. Work isolated night shifts, with minimal circadian disruptions.
3. Consider the Thomas schedule for groups: One physician works extended night schedule for 1 month or longer, with isolated nights off being covered by the other group members.
4. Schedule shift rotations in a clockwise direction, with 1-month minimum time per rotation.
5. Eight-hour shifts are preferable to 12-hour shifts.
6. Sleep in a darkened room; minimize disruptions.
7. For those unable to maintain consistent sleep patterns, use compromise strategies such as anchor sleep, split sleep periods, or napping to mitigate circadian disruptions.
8. Start the awake period with a high-protein meal, switching to complex carbohydrates toward bedtime. Avoid caffeine and high-calorie, high-fat snack food before sleep. Eat meals regularly.
9. Use bright light (>10,000 lux) for 2 hours after arising as an adjunct in adjusting to new shifts.
10. Exercise regularly.
11. Plan regular “quality time” with family and friends.
12. Do not try to live a day shift lifestyle while working night shifts.
event in thoughts, dreams, or daily life; an avoidance of any stimuli associated with the event; a sense of numbness to one’s emotions; and a wide variety of other symptoms, including sleep disturbance, irritability, anxiety, and loss of emotional control.45

The concept of critical incident stress debriefing has evolved over the past 30 years from the combined experiences of a variety of emergency services and military personnel. The two main goals of debriefings are to lessen the short-term emotional impact of distressing events and to accelerate recovery from such events before stress reactions occur. As originally described, debriefings are structured group meetings that emphasize venting of emotion and discussion of other reactions to a critical event.46 Formal critical incident stress debriefing teams are available in many communities through local emergency medical services agencies. Debriefings also can occur on an informal basis in the ED. Such sessions can take the form of impromptu meetings of emergency and rescue personnel involved in specific incidents in which the details of a particular event and its associated emotional content are expressed and shared among members of the team.43 It is important for those involved in leadership roles to make some form of critical incident debriefing processes available when such events occur.

**Family and Social Relationships**

Many physicians are overly dedicated to their work and prone to delay sources of emotional gratification outside the work environment. These qualities, which may promote a high degree of professional success and satisfaction, also may interfere with the development of family and social relationships, a problem that may be compounded for emergency physicians by their irregular hours.57-49 The ability to develop and sustain intimate relationships may be the most critical element in any wellness formula. The simplest and most profound way to maintain mental health while actively absorbed in a demanding career is to establish and cultivate a viable and genuine relationship with a caring, emotionally expressive spouse or significant other. The promotion of a close family relationship involves, at the very least, a willingness to assign and prioritize protected time with spouse and other family members. For many physicians, it also involves a conscious effort to develop communication skills, particularly with respect to active listening and the open expression of feelings.49

**Physical Fitness**

Physical fitness is an important concern for emergency physicians, given the rigors of a typical emergency medicine practice. Unfortunately, the obstacles to developing a comprehensive fitness program may be considerable. Factors such as irregular hours, hectic work pace, and the variable quality of hospital menus complicate the task of establishing and maintaining exercise regimens and healthy dietary habits. The impact of proper diet and exercise on a variety of wellness parameters is clearly established. Documented benefits of an appropriate diet include lower cholesterol levels, weight control, augmented blood pressure control, and a lower incidence of certain cancers. The American Heart Association (AHA) periodically provides dietary guidelines, as summarized in Box 203-3.50

The benefits of a regular and vigorous aerobic exercise program include enhanced exercise tolerance, cardiovascular fitness, lower blood pressure, increased high-density lipoproteins, decreased triglyceride levels, augmented weight reduction efforts, lessened anxiety and depression, improved glucose tolerance, and enhanced endurance, flexibility, and strength. According to current AHA guidelines, cardiovascular fitness is best maintained by a program of aerobic exercise (the repetitive use of large muscle groups) three to six times per week for at least 30 minutes per session. Strength-developing activities (resistance training) should be performed at least twice per week, with 8 to 10 exercises that use the major muscle groups of the legs, trunk, arms, and shoulders. A regimen of one or two sets of 8 to 12 repetitions of each exercise is recommended. The exercises should be vigorous, sufficient to raise heart rate to at least 50% of maximum (recommended average maximum heart rate is 220 minus age).51

**Relaxation and Renewal**

In dealing with the innumerable stresses of emergency practice, emergency physicians must be equipped with considerable emotional resources, derived in part from strong peer and personal support systems. Methods of relaxation and renewal are important additional elements.6,34,36

Emergency physicians must continually cultivate the ability to remain functional and emotionally resilient when facing the turbulence of the typical ED. Physiologic correlates of stress—increased heart and respiratory rates and increased blood pressure, oxygen consumption, and serum lactate level—can be normalized by a variety of relaxation techniques. These include prayer, Zen, yoga, transcendental meditation, autogenic training, and progressive relaxation. Studies indicate that the regular use of such techniques can allow development of considerable control over the relaxation process.32-54

A final element in the promotion of wellness and lifestyle balance is the concept of renewal. Physicians typically develop a work ethic that makes it difficult to disengage from medical responsibilities. A single-minded devotion to career ultimately is impoverishing, and by neglecting restorative activities, physicians tend to lose their emotional resilience.34,35 The concept of renewal involves the ability to prioritize and establish time for rest and revitalization, as well as spiritual, emotional, and intellectual growth. Out of the maelstrom that constitutes a typical day in the ED, emergency physicians should look to sources of renewal as key elements in their formula for lifestyle balance.
Many aspects of the practice of emergency medicine are potentially unhealthful. Emergency physicians can hope for less stressful, more fulfilling careers by adopting strategies to enhance personal and professional well-being.
